Diacetyl Metabolism. During the propagation phase the yeast cells need numerous nitrogen compounds for the formation of yeast protein. If there is not sufficient fixed nitrogen present in the wort in the form of compounds which can be assimilated, the yeast will use a combination of carbohydrate and protein metabolism. During the valine synthesis diacetyl can be formed via 2-acetolactate by oxidative decarboxylation as shown in Figure 11. This step, which is catalyzed by yeast enzymes, is highly temperature-dependent, and occurs very slowly below 10 °C. Diacetyl itself is present in very small quantities in fermentation samples and in green beer, because its reduction to acetoin is much faster than its formation. The final product 2,3-butanediol is, as far as taste is concerned, unobjectionable; its concentration in beer never exceeds its flavor threshold. Bacteria, which may occur in the brewery as infections, also are likely to promote the formation of diacetyl by the route shown in Figure 11. Some types of bacteria contain an enzyme which can decarboxylate 2-acetolactate directly to acetoin while avoiding the limiting maturation step.

Fermentation Conditions. The formation and reduction of 1,2-diketones is dependent on (1) a sufficient supply of free amino nitrogen and other yeast nutrients, (2) proper pitching and doubling conditions (sufficient aeration, low pitching temperature, optimization of pitching rate regarding yeast quantity and timing), (3) a careful selection of the yeast (yeast strain, physiological condition of the yeast, no infection), and (4) control of the fermentation and maturation conditions favorable for the degradation of diacetyl. The most effective parameter in this respect is temperature control during fermentation and maturation, which is the basis for the fermentation procedure shown in Figure 12.

Using the combination of *cold fermentation – cold maturation*, a tasty beer can be produced by simple means. It is advantageous to remove most of the yeast at the end of fermentation and to achieve secondary fermentation by the addition of "krausen" (green beer in its initial fermenting stage).

If the combination of *warm fermentation – warm maturation* is considered, the formation of fermentation byproducts is increased at the prevailing high fermentation temperatures. The rapid pH drop results in losses of bitter substances, decreased foam stability, and an unsatisfactory yeasty flavor. Pressure fermentation using carbon dioxide is a remedy. This will slightly decrease the fermentation rate and control yeast propagation, thus curbing the formation of fermentation byproducts.

The combination *cold fermentation – warm maturation* avoids the formation of undesirable flavors and decreases the level of diacetyl safely; it leads to beer of constant quality. In this case, temperature control is optimally adjusted to the metabolism of the yeast. In *programmed maturation*, heat exchangers are used in order to raise the temperature to 20 °C. The addition of 10 % "krausen" with an apparent degree of attenuation of 20 – 30 % is practiced at the beginning of this maturation phase. Accelerated fermentation and maturation are also achieved by stirring fermentations and then maintaining a maturation step and subsequently purging green beer with carbon dioxide. However, an excess of fermentation byproducts is formed by this method.

Fermenters. Fermentation and maturation are carried out in open or closed fermenters, horizontal tanks, or vertical fermentation tanks with conical bottoms [39]. In two-tank processes, fermentation, maturation, and storage occur sepa-

Figure 12. Fermentation in practice
A) Cold fermentation – cold maturation. B) Warm fermentation – warm maturation. C) Cold fermentation – warm maturation

rately; vertical tanks with conical bottoms are used in this case.

The capacity of the cooling equipment and heat exchange surface of the tanks should be designed for maximum heat development or, in the case of single-tank processes, for a maximum cooling rate.

Fermentation Stages. The brewer identifies the changes occurring in the green beer by carefully observing the individual fermentation stages: the creaming, the head formation, the rocky head, and the decreasing of head at the end of fermentation. Extract decrease and temperature level must be checked constantly. Attenuation also is indicated by a fall in pH value, by a phase of cell propagation and cell sedimentation (turbidity), by a decrease in coloration, and by a lowering in redox potential.

The carbon dioxide formed during fermentation amounts to 2 – 2.5 kg per hectoliter of beer. It is collected and can be used for carbonation of soft drinks or for low-oxygen bottling and racking.

3.3.3. Cold Storage

During cold storage the beer must be carbonated to the desired CO_2 level (0.48 % for draft beer, 0.50 % for canned beer, 0.55 % for bottled beer). This can be achieved in the conventional procedure by using a definite bunging overpressure of 0.2 – 0.6 bar, depending on hydrostatic pressure and temperature. Beers that underwent warm maturation require either higher pressure, or carbon dioxide to be added during transfer from warm to cold storage tanks. During storage, the beer must clarify by allowing the yeast and other haze-causing materials to settle, and its taste must refine and round off. In order to achieve these requirements, the beer must be stored at 0 to $-2\,^{\circ}$C during the last week or two. When warm maturation is practiced, the storage period cannot be as easily defined. Frequently fermentation, maturation, and storage take place in the same vessel (one-tank process).

By using separate tanks for the sedimentation of the yeast after fermentation (flocculation tanks), yeast content and degree of attenuation are further balanced. During transfer to the cold storage tanks krausen is added. Separate storage tanks also are used when the beer is stabilized with bentonite during the second half of the storage period.

Continuous fermentation may be accomplished by through-flow or by tributary-flow systems or in a bioreactor. These methods are rarely found in large production facilities.

3.3.4. Filtration

For filtration theory and beer filtration, see [40].

Besides an impeccable taste, perfect clarity is expected of a stored and matured beer. Solid and hazy particles still present in the beer (yeast, protein – tannin particles, and hop resins) are removed by filtration. Filtration also improves biological and chemical-physical stability. Filtration is carried out at low temperature (possibly at 0 to $-2\,^{\circ}$C) under a counterpressure of carbon dioxide above its saturation level, and with minimum uptake of oxygen [42].

Filtration systems used for pre-clarification were formerly pulp filters; today brewers use mostly plate and frame filters, pressure leaf filters, or candle filters for cake filtration with a filter aid (diatomaceous earth [41], perlite), or centrifuges. For subsequent final clarification and sterile filtration, sheet filters made from cellulose and diatomaceous earth are used. For sterile filtration filter membranes made from cellulose esters of definite pore size may be used.

The choice of the clarification method depends on capacity, technical considerations, and economic conditions. Another factor is the filterability of the beer, which is not always proportional to the viscosity, but also depends upon the nature and amount of filtration-retardant materials present, such as α- and β-glucans, proteins, and a high yeast content.

3.3.5. Stabilization

In bright beer high molecular proteins and tannins tend to aggregate and form haze. This process can be delayed by removing one of these fractions which improves the chemical-physical shelf life of the product. Most common is the removal of part of the tannins by adding polyvinylyrrolidone (10 – 50 g/hL) as an adsorbent. Polyvinylpyrrolidone is dosed in the filtered

beer and retained in a pressure leaf filter. The loaded polyvinylpyrrolidone is subsequently reprocessed and reused.

3.3.6. Types of Bottom-Fermented Beers

In many countries, bottom-fermented beer is designated as *lager beer* [43]. Its extract of original wort varies according to local laws (tax classification) from 7 to 14 %. Lager beers are the most popular, with an average bitter substance content of 20 EBC bitter units (see Table 7 and Section 5.3).

Table 7. The composition of bottom-fermented pale lager beer (12 % extract of original wort)

Extract of original wort	12.0 wt % (125.6 g/L)
Attenuation limit (apparent)	78 – 85 %
Real degree of attenuation	65 – 80 %
Apparent residual extract	1.7 – 3.0 wt %
Real residual extract	2.0 – 3.5 wt %
Alcohol concentration	3.5 – 4.5 wt %
Total nitrogen	700 – 900 mg/L
Coagulable nitrogen	8 – 28 mg/L
High molecular mass nitrogen	150 – 250 mg/L
Low molecular mass nitrogen	300 – 600 mg/L
Free amino nitrogen	80 – 160 mg/L
Bitter substances	16 – 25 EBC bitter units
Total polyphenols	130 – 180 mg/L
Anthocyanidines	40 – 80 mg/L
pH	4.3 – 4.6
Viscosity (20 °C)	1.4 – 1.7 mPa · s

Beer with an Extract of Original Wort of 10 – 14 %. This range comprises an extraordinarily large variety of beer types, including pale and dark beers, export beers (more than 12 % extract of original wort), Märzen beers, special beers, and festival beers (13 – 14 % extract of original wort). Within these limits there are such different beer types as Pilsener, Dortmunder, Munich, as well as smoky-flavor beers and cellar beers; these are however restricted to certain localities. The upper gravity limits for special beers differ from country to country: for instance, In Germany 14 %, in Austria 13 %, in Italy 14 %, and in France 15 %.

Strong Beer. In Italy, pale and dark beers of more than 15 % extract of original wort are classified as strong beers; in Austria and Germany beers from 16 % up to a maximum of 28 % extract of original wort also belong to this class.

3.4. Top Fermentation

Top-fermented beers differ from bottom-fermented beers by their special aroma which is primarily induced by the top-fermenting yeast strains of *Saccharomyces cerevisiae*. The particular yeast strain employed has a higher optimum fermentation temperature, and therefore the fermentation proceeds between 12 and 25 °C. During fermentation, the yeast rises and can be skimmed off the top. In large vessels, especially the cylindrical fermentation tanks with conical bottoms, the yeast is, however, cropped in the same manner as in bottom fermentation. The number of yeast generations is considerably greater. At the higher fermentation temperature, the amount of diacetyl is usually easily decreased. Because of the fast rate at which fermentation proceeds, a relatively low pH value of 4.1 – 4.3 results.

Types and Production of Top-Fermented Beers.

Wheat Beer [44]. The extract of original wort in wheat beer is 11 – 14 %; the wheat malt portion can range from at least 50 to 100 %. An intensive two-mash decoction procedure is needed in the brewhouse in order to ensure a satisfactory protein modification, because an increase in wheat malt proportionally decreases the concentration of assimilable nitrogen compounds in the wort. Because of the higher pitching temperature (12 – 18 °C), the pitching rate required will be lower (0.3 – 0.5 L of yeast per hectoliter of original wort, corresponding to $7 - 15 \times 10^6$ yeast cells per mL). The aeration should ensure an oxygen concentration of 6 – 8 mg/L. The initial fermentation stage is characterized by the rise of trub particles and hop resins to the surface. After their removal, yeast rises to the top and can be cropped; this continues until the end of fermentation. The special wheat beer yeast can be repitched as often as 200 – 500 times. Wheat beer is characterized by a typical spectrum of fermentation byproducts, such as 4-vinylphenol and 4-vinylguaiacol; these two compounds are responsible for the typical aroma of wheat beer. A more rapid and extensive pH drop, an increased formation of higher alcohols and esters, together with a greater decrease in nitrogen and bitter compounds, mark the course of wheat beer

fermentation as compared with lager beer procedures. A higher bunging pressure during storage ensures a carbon dioxide concentration in wheat beer of 0.7 – 0.9 %. If wheat beer is marketed as "naturally hazy", the secondary fermentation can be accomplished in the bottle by adding unfermented wort and bottom-fermenting yeast or bottom-fermented krausen. Crystal-clear wheat beer remains in the tank until mature and is subsequently filtered and bottled.

Alt beer also has an extract of original wort of 11 – 14 %. Methods vary widely for the production of the dark Alt beer which gives readings of 25 – 40 EBC coloring units: the wort may be produced from pale malt with the addition of caramel coloring or colored beer, 100 % dark malt, or 90 % pale malt and 10 % dark caramel malt. A proportion of 10 – 15 % pale wheat malt sometimes is used to round off the taste. The black malt which is used as a substitute for caramel may also be produced from wheat. The bitter substance concentration of Alt beer amounts to 28 – 40 EBC bitter units. The fermentation temperature is 12 – 22 °C.

Kölsch beer (extract of original wort 11 – 14 %) may be produced only in the town of Cologne. It is brewed with pale barley malt by adding up to 10 – 20 % wheat malt, and fermented at 12 – 22 °C, but sometimes up to 28 °C. The character of Kölsch and Alt, formerly designated as top-fermented bitter beers, is strongly determined by the properties of the specific yeasts; a large variety of flavors results.

Berliner Weisse (White) also is named after its place of origin; it has an extract of original wort of 7 – 8 %. Its very low pH value of 3.2 – 3.4 originates from the combined yeast and lactic acid fermentation. A degree of attenuation sometimes exceeding 100 % results in an alcohol concentration of 2.5 – 3 % and a lactic acid concentration of 0.25 – 0.8 %. The bitter substance content amounts to 4 – 6 EBC units, whereas the carbon dioxide concentration lies between 0.6 and 0.8 %. The beer has an acidic taste, which is marked by a pleasant estery – flowery quality, depending on the production method and the particular type of beer; it is frequently served with raspberry or woodcruff syrup.

Malt Beer. Sugar and sugar syrup may be used in the production of top-fermented nutrient beers. The beers are brewed with 7 – 8 % extract of original wort, and are enriched after filtration with sugar until an extract of original wort of 12 % results. The alcohol concentration of malt beer must be under 0.5 %. The pH lies between 4.5 and 4.9 depending upon the method of wort production and the degree of attenuation; the carbon dioxide concentration is 0.4 – 0.5 %, the color rating ranges from 50 to 80 ECB units (65 – 80 % dark malt, 3 – 5 % dark caramel malt, 3 – 5 % acid malt, and the remainder pale malt) and the bitter substance content is 6 – 10 EBC units. Malt beers are pasteurized on account of their high content of fermentable sugar.

British Ales. British ales have an extract of original wort of 7 – 13 %, according to the tax category. Depending on the type of malt charge and adjunct (mostly corn), on the choice of top-fermenting yeast strains, as well as on the "primings" added in the cold storage tank (caramel coloring), various types are obtained such as ale, brown ale, and bitter ale. The so-called "best bitter" is remarkably bitter due to special hopping methods; it also possesses a strong hop aroma. Bottled and canned beers are filtered, carbonated, and stabilized, according to the demands of the market. The original draft ale is clarified with gelatine or isinglass, and dry-hopped in the barrel or keg.

Stout is a dark, strongly hopped beer, with an extract of original wort between 11 and 18 %. The weaker stouts also are called *porter*. Some of these are treated with a special post-fermentation yeast (*Saccharomyces brettanomyces*), which imparts a typical aroma to the product.

Geuze and *Lambic* are Belgian spontaneously fermenting beers with an extract of original wort of 11 – 12 % [45]. They are produced from certain admixtures of raw materials other than malt. The hop content varies widely, as does the method of wort production. Fermentation is not caused by a definite yeast strain, but by the airborne organisms of the fermentation rooms and vessels. Because of this spontaneous fermentation, the beers vary not only in their alcohol level, but also in their lactic acid concentration. According to the amount of acidity, the beers are either left in a natural state and consumed with added sweeteners, or a specific amount of sweet mash is added.

Top-fermented strong beers with an extract of original wort of more than 16 % include the

German pale and dark *Weizenbock* beers as well as the different varieties of stout.

3.5. Special Production Methods

A number of special production methods have been designed to produce beers with very specific properties. The legal regulations covering such products differ in various countries.

3.5.1. Dietetic Beer

Dietetic Beers are pale beers of Pilsener brewing type; in Germany they may contain only 0.75 g bioavailable carbohydrates and 0.5 g protein per 100 g of beer. In order to achieve these figures, wort of 11 – 12 % extract must be fermented until the apparent degree of attenuation is more than 100 %. Brewhouse procedures are adapted towards achieving this aim by employing mashing with extended rest periods at 60 – 66 °C. During cold fermentation (7 – 12 °C), a small proportion of malt extract that has been drawn from the mash at 50 °C is added. This causes breakdown of the remaining high molecular mass carbohydrates and proteins. The addition of malt flour also has proved successful in obtaining the properties of dietetic beer. The beer must be carefully stabilized because the addition of unboiled extracts increases considerably the amount of coagulable nitrogen compounds. Almost complete breakdown and fermentation of the extract results in the alcohol concentration rising to 4.8 – 5 %. This is partly viewed as a disadvantage. Thus, the alcohol concentration is subsequently lowered by either distillation in film evaporators or reverse osmosis. It is much easier to produce dietary beer with a lower extract of original wort because the control of both alcohol concentration and fermentation is simpler. The intensive fermentation leads to pH values in the range of 4.1 – 4.5; the bitter substance content varies between 22 and 40 EBC units.

3.5.2. Nutrient Beer

Nutrient beers are bottom-fermented beers which are brewed with 100 % malt. They are classified either as "low-alcohol" (alcohol concentration under 1.5 %) or as "alcohol-free" (alcohol concentration under 0.5 %). The extract of original wort of these very dark beers (60 – 80 EBC coloring units) is between 11.5 and 12.7 %; the apparent degree of attenuation is 25 – 30 % in the low-alcohol beer and 8 – 10 % in the alcohol-free beer. The pH is 4.7 – 4.9, according to the degree of attenuation and other technological steps (acid malt); the bitter substance content is low (6 – 10 EBC units). The flavor of alcohol-free nutrient beers may be improved by increasing the alcohol concentration to 0.7 % and then blending with first-wort extract before filtration. It is also possible to remove the alcohol partly. Complete pasteurization of such beers is mandatory.

3.5.3. Low-Alcohol Beer and Alcohol-Free Beer

The many varieties of low-alcohol beers may be divided into three groups:

1) Beers where the fermentation is stopped by filtration and pasteurization. An alternative to heat treatment is a *cold shock process*, during which a beer that has just started to ferment is rapidly cooled in a thin film. This produces a spectrum of fermentation byproducts similar to that of normal beer.
2) Beers that are fermented with a special yeast strain, e.g., *Saccharomyces ludwigii*; these yeasts metabolize only hexoses and sucrose. The major fraction of the malt sugars, such as maltose and maltotriose, remains unfermented.
3) Beers that are fermented almost normally, but where part of the alcohol is later withdrawn by thin-film evaporation, vacuum distillation, reverse osmosis, or dialysis.

They latter two methods are currently the most common ones, because the taste of the dealcolized beer is more similar to that of normal beer.

3.5.4. High-Gravity Brewing

This procedure is popular because existing installations can be better utilized and because a higher capacity can be achieved without new investment [43]. In general, the wort is brewed

as strongly as the brewhouse equipment will permit, e.g., with 13 – 18 % extract of original wort instead of 11 – 12 %. Concentrations of 16 – 18 % are only attainable without loss of yield if syrups are added at the end of wort boiling. After fermentation and maturation, these stronger beers are adjusted to the desired extract of original wort with carefully processed water (deaerated, carbonated, and sterilized). The wort concentrations are usually no higher than 14 – 1 5 % so as to maintain the ratio and level of byproducts and, thereby, the normal beer taste. High-gravity beers always have a poor head retention.

3.6. Filling

After filtration, all operations must be directed to maintain the quality of the beer. Mistakes made at this point are very hard to rectify and will only become noticeable much later (re-infection and aged taste caused by a high oxygen concentration). Furthermore, the beer must be bottled under an appropriate pressure to prevent the escape of carbon dioxide. Filling and packaging are subject to various legal regulations just as the production of beer itself. These regulations pertain to labeling, container capacity, and volume tolerance.

The amount of beer lost depends on the production facilities, and to a certain extent on capacity, and ranges between 3 and 10 %. Examination of *beer loss* provides an insight into loss of volume, which occurs from casting to the actual process of bottling, and into loss of extract.

Kegging. Barrels are manufactured of oak wood, aluminum alloys, stainless steel, or synthetic materials lined with stainless steel; their size ranges from 10 to 250 L. After the barrel has been thoroughly cleaned, it is purged with carbon dioxide or, less advantageously, with air, and filled under counterpressure (isobarometric). Bowless filling units not only avoid the danger of infection, but they also protect the beer from extensive contamination with oxygen.

Barrels with a cylindrical edge are called *kegs* or *system barrels*; they have a permanently installed fitting for cleaning, sterilization, filling, and tapping. With such a device, the barrel remains sealed and under a pressure of carbon dioxide even after it has been emptied. In this fashion the drying-up of beer remnants is avoided, and cleaning is facilitated. Cleaning and filling under sterile conditions are easily automated. Kegs and fittings are standardized.

Cellar Tanks. For larger distributors stationary draft beer tanks which hold 10 to 30 hL can be installed. The beer is delivered from the brewery in large tank trucks. The cellar tanks are equipped with cooling devices. They are lined with disposable polyethylene bags, which makes it possible to store the beer under impeccable sanitary conditions without the need to clean the cellar tank. The excess pressure necessary to dispense the beer is created by gas which is admitted between the inner wall of the tank and the polyethylene bag.

Bottling. Bottles may be made of glass or plastics [poly(ethylene terephthalate), PET, or poly(ethylene naphthalate, PEN)]. Whereas glass is diffusion-proof, not only can carbon dioxide escape from plastic bottles, but also oxygen can diffuse into the beverage, and cause an undesirable oxidation taste. A metal crown with synthetic liner is widely preferred over other means of sealing the bottles. Returnable bottles must be cleaned to a microbiologically impeccable standard before refilling. The step can be preceded by a steam treatment. Disposable bottles are relatively expensive because their manufacture requires more energy and raw material than multiple-use bottles.

Isobarometric bottling of glass bottles is best carried out by pre-evacuation of the bottles, intermediate puging with carbon dioxide, second evacuation, counterpressurizing and then filling. After filling fobbing is induced by various means; this provides for a maximum displacement of air. The crown closure machine presses the crimped edges of the crown around the mouth of the bottle, which is then labeled automatically. Modern bottling machines fill up to 120000 bottles per hour. Brown glass bottles are preferred to those made of green glass, because brown bottles protect the beer better against light of short wavelengths, which causes photodegradation of the bitter acids of hops, and hence gives rise to a “light stroke”.

Canning. Cylindrical cans of aluminum or tinplate are closed with a flat lid equipped with a ring pull-tab. A nonporous synthetic resin coating is applied to the inside of the can so as to prevent a chemical reaction occurring between the metal and the liquid. Pre-evacuation is only possible with stable tinplate cans. Otherwise cans are purged with an inert gas and carbon dioxide is blown under the lid of the can before sealing.

3.7. Beer Dispensing

After filling and transportation the beer should be stored at a temperature of 6 – 9 °C without movement. Bottled beer should be stored in the dark. For draft beer it is important to maintain the carbon dioxide level established in the brewery right up to the end of dispensing, and moreover to transfer the carbonation into the glass without loss. This is achieved by dispensing the beer with a carbon dioxide pressure higher than that of the saturation pressure in combination with a pressure compensator [46]. The clean, thin-walled glasses used exclusively for beer drinking should be rinsed with fresh, cold water just before the beer is tapped so as to equalize the temperature. Special care should be taken in the cleaning of beer glasses in order to remove traces of fat which might otherwise cause premature collapse of the sensitive foam, and also to maintain the good flavor of the beer.

4. Properties and Quality

Foam. More than any other beverage, beer is marked by its natural ability to form foam [46]. The release of carbon dioxide during tapping is responsible for foam stability whereas the sparkling of carbon dioxide bubbles in the tapped beer is responsible for head retention. Both foam stability and head retention, as well as the liveliness of the beer, depend largely on the carbon dioxide concentration. A foam-stabilizing effect is ascribed to colloids, such as glycoproteins, tannins, β-glucans, and isohumulone complexes; on the other hand, fatty acids, glycerides, and ethanol in an amount in excess of 7 – 8 wt % destabilize foam.

Color. The color of beer is first of all determined by the malt type. During the brewing process an increase in color is caused by temperature-dependent, nonenzymatic color reactions of the Maillard type; these occur especially during kilning of overmodified green malts treated with gibberellic acid. The beer is further darkened during boiling of mash portions and of wort, during the thermal stand of the wort, and also by oxidation reactions during wort preparation and bottling. A paling of the beer color occurs during fermentation, as well as later during filtration.

Buffering and Reduction Potential. The buffering substances present in the beer are chiefly weak acids and their salts, primary and secondary phosphates, and proteins. Depending on their chemical identities and concentrations, they can counteract the pH changes that occur during malting and during wort preparation, and they can attenuate the pH drop during fermentation. The reductones that are formed during malt, wort, and beer production are of great importance for the stability of the beer. By adding antioxidants, the reduction potential can be increased further.

Sensory Qualities. The odor and the taste of the beer, as well as the mouthfeel, are evaluated with regard to quality and intensity by taste experts. The temperature of the beer during tasting should be 6 – 10 °C. In a taste evaluation one differentiates between the *initial impression*, for which the aroma and palatefullness are mainly responsible, the *tingle* or *sparkle*, where the impression of freshness emerges (a function of carbon dioxide release and the organic acids present), and the *aftertaste*, where the quality and intensity of the bitterness are put to the test. Taste experts must be selected carefully and their sensory skills constantly practiced [22]. An international nomenclature with guidelines for the description of the impressions of beer flavor has been developed [47], [48]. Five basic types of flavor evaluation methods exist [47]:

> *Differentiation tests* are used to find out (a) if there is a difference between two or more samples, or (b) if two or more samples are identical to each other.

Descriptive tests are applied to "measure" the sensory quality of one or more samples using a vocabulary of flavor terms.
Scaling tests rank the intensity of one or more beer flavor attributes
Preference tests are performed by consumers to generate a simplified determination of beer flavor or to assess a preference.
Drinkablity tests indicate the relation between the brewing process and the consumer's judgement of drinkability.

Flavor Stability. After bottling the beer, numerous changes in its original properties occur. The changes in palatefullness and in liveliness are caused by an agglomeration of colloidal particles, which in turn is facilitated by oxygen and by changes in temperature. Palatefullness declines, and the bitterness becomes coarser and broader. Beer aroma undergoes a change due to numerous reactions contributing to an "aged" quality, which is also described as oxidation or bready flavor [49], [50].

5. Analysis

5.1. Analysis of Raw Materials

5.1.1. Water

In the food-processing industry, drinking and process water must comply with certain quality standards from the bacteriological, hygienic, and chemical point of view. The hardness of water can be determined by complexometric titration, which gives an idea of the concentrations of carbonate, hydrogen carbonate, and hydroxide in the water. The calcium and magnesium hardnesses must be determined to estimate the residual alkalinity.

5.1.2. Malt

The congress mashing method is used to study the parameters that determine the modification properties of the malt. In this method, ground malt is subjected to a simple infusion mash process whereby the temperature must first be maintained at 45 °C for half an hour, and is then gradually increased at the rate of 1 K/min to 70 °C; this temperature is finally maintained for one hour.

The fine – coarse difference is calculated from the dry matter extract of finely and coarsely ground malt. The degree of protein modification is the ratio of the amount of dissolved nitrogen compounds to the total nitrogen content of the malt (as determined by the Kjeldahl method).

Microscopic staining in combination with statistical methods is being increasingly used to estimate the uniformity of modification. Other qualitative characteristics are the enzyme potential, friability, and purity of the barley variety.

5.1.3. Hops and Hop Products

The bitter ingredients can be isolated by the fractionation of resins or by using HPLC. During the fractionation of resins, hop ingredients are distributed between an acidic aqueous methanol phase and diethyl ether. The bitter ingredients, which are extracted into the ether phase, are classified according to their solubility in methanol and hexane into total resins, soft resins, and hard resins. Depending on their ability to form lead salts the soft resins are further classified into α- and β-fractions. Using the HPLC method each of the homologues of the α- and β-acids and their oxidation products can be separated [3].

5.2. Brewhouse Control

The yield of the as-is extract (air-dried) from the congress mashing method is a measure of the yield achieved in the brewhouse during the large-scale preparation of the wort. For this the extract of original wort and the quantity of the cast wort must be determined.

5.3. Wort

The chemical composition of the wort is also of interest; amylolytic degradation and saccharification of starch components should be advanced in such a manner that only very few compounds that are stainable with iodine remain in the wort . When turbid lautering occurs, further stainable starch particles are solubilized during wort boiling. Furthermore, turbid lautering also leads to

an increase in the long-chain fatty acids content in the wort.

The gum content of the wort (determined by precipitation with salts, or precipitating agents or after isolation, using gel permeation chromatography) can only slightly be influenced by the choice of the mashing procedure. It depends mainly on the initial gum content of the barley and on the modification of the malt.

The degree of protein degradation during mashing can be measured from the contents of amino acids and dipeptides in the wort and from a fractionation of the nitrogen compounds. The amount of coagulable nitrogen and the quantity of precipitated trub give information on the intensity of wort boiling. An idea of the various Maillard reactions, which take place during boiling, is given by the concentrations of the aroma compounds in the wort (carbonyl compounds, alcohols, Maillard products), which are quantitatively determined using GC.

The isohumulones are the most important bitter compounds in the finished wort and in the beer. They are extracted from the acidified sample with isooctane, and their concentration is determined by spectrophotometry. The extinction of the isooctane extract at 275 nm is multiplied by 50; the value thus obtained is taken as the bitterness (in EBC bitter units) according to the standards of the European Brewery Convention (EBC) and the American Society of Brewing Chemists (ASBC).

The attenuation limit is determined by fermenting a wort sample with an excess of yeast at room temperature.

5.4. Fermentation

The most important parameters during fermentation are the decrease in extract, the pH, and the temperature. The practice of keeping a record of the yeast cell concentration from pitching to the end of fermentation using the electronic Coulter counter or microscopic count methods (Thoma chamber) is gaining increasing importance.

Gas chromatographic methods have proved to be useful in estimating the aroma components. Whereas the more concentrated fermentation byproducts in the ppm-range can be used to judge the fermentation and eventually occurring organoleptic deviations, certain trace components in the ppb-range can serve as indicator substances for the identification of the process technology. The acetoin concentration is used as an indicator for the vitality of the yeast. After a relatively simple work-up method (steam distillation of the sample followed by extraction of the distillate with dichloromethane) about 60 individual components can be detected in a single run using modern GC and high-resolution capillary columns. Along with selective detectors (sulfur detector, nitrogen detector), this figure can be increased considerably.

5.5. Microbiological Process Monitoring

In a brewery the main contaminants are lactobacilli, *Pediococcus cerevisiae*, and "wild yeasts" (*Saccharomyces* species). Gram-negative bacteria (genus *Megasphaera* or *Pectinatus*) may also be dangerous [24].

Direct viewing under the microscope, biological shelf life tests, and enrichment methods are used. Shelf life tests show microbiological stability of the beer during a storage at 27 °C. The yeast sediments of samples taken from the fermentation and the storage cellars are observed under the microscope after a period of about 20 days. In the case of filtered samples, trace infections are detected by enrichment on a solid or liquid nutrient medium. By using membrane filtration techniques, the microorganisms on the filter are incubated anaerobically under optimal growth conditions on solid agar. The samples can be evaluated after an incubation period of two days with aerobic incubation (wort agar) and five days (NBB agar; NBB = culture medium for bacteria harmful to beer) with anaerobic incubation. Color changes in liquid NBB broth or solid NBB agar indicate the presence of harmful bacteria.

The number of biological controls and the choice of culture media depend on such factors as selectivity, specificity, and output of the brewery. As a routine procedure, the pitching yeast as well as bottled beer stored for a specific period should be analyzed.

5.6. Beer

The extract of original wort of the finished product can be calculated from the density and re-

Table 8. Beer production, exports, imports, consumption and per capita consumption in 2000 (countries are ranked in the order of decreasing overall consumption

Africa				64.1	6.4
World total				**1386.3**	**22.6**

fractive index of the decarbonated beer or from the densities of beer distillate and the distillation residue.

The methods described in Section 5.3 are also used for beer. The carbon dioxide content is determined by measuring the total pressure of beer after vigorous shaking at a specific temperature.

The physicochemical stability of the beer is estimated from an accelerated aging process. In this method filled beer bottles are kept alternately at 40 °C (or at 60 °C for stabilized beer) and at 0 °C until an increase of turbidity by 2 EBC formazine units occurs after cooling. By multiplying the obtained stability period – expressed as 40 °C- (or 60 °C-)warm days – with a factor that is specific to each brewery, one can calculate the period of time during which the beer would not become turbid under normal storage conditions.

The carbon dioxide content of the beer determines its foaming capacity. The head retention is dependent on the composition of the beer. The methods of foam measurement are classified according to the way the foam is generated: (1) free fall, (2) shaking, (3) bubbling of a gas, and (4) catalytic release of carbon dioxide.

Color can either be measured by visual comparison under defined conditions or spectrophotometrically by measuring the extinction of the sample at 430 nm and that at 700 nm; this difference, multiplied by 25.5, is defined as the color in EBC color units.

5.7. Legally Required Controls

In order to comply with the requirements of the food laws, the extract of original wort or the alcohol content must be within certain limits. Further, the filling volume in the bottles must be within required tolerances. Nevertheless, it is still indispensable that the brewmaster is responsible for determining by taste test whether the beer is ready for filling and before it leaves the brewery.

In the last years breweries introduced integrated management systems and had them validated by a external accredited and recognized certification body. The following systems have been introduced [51], [52]:

Quality Management Systems in accordance with DIN EN ISO 9001 (design, development, production, installation, and maintenance),
Environmental Management System in accordance with DIN EN ISO14001,
Working Security System, and

Table 9. Top world breweries

	Production, 10^6 hL/a	Regional ranking	Leading brands

Hazard Analysis Critical Control Points (hygiene in food producing companies)

6. Economic Importance

During the period of 1991 – 2000 beer output increased by more than 20 % worldwide. Despite stagnation in several large beer consuming nations the total market size of 1386×10^6 hL reached a new peak in 2000. The per capita consumption increased only marginally, to reach 22.6 L in 2000 [27].

The most popular product is the pale, bottom-fermented lager of typically 4.5 – 5.5 vol % alcohol. Worldwide 65 % of the beer is marketed in bottles, 22 % in cans and 13 % in kegs or barrels (draught beer).

Because the cereals produced in the individual countries are not exclusively used for malting and brewing, it is not possible to list which and how much of the different cerials are used. The world crop of hops in 2001 was 97 730 t (62 % bitter hops, 38 % aroma hops). The content of α-acids was about 8 % on average, so 7928 t of α-acids were harvested. Production and consumption figures are given in Table 8, Table 9 lists the top brewers of the world and their leading brands.

A survey of the productivity and quantities of energy and water consumed in breweries of different sizes is given in Table 10.

Table 10. Productivity and specific energy and water comsumption as an function of brewery size

	Breweries with an annual output of		
	$> 10^6$ hL	$> 10^5$ hL	$> 10^4$ hL
Productivity, hL per employee	7000	3000	1000
Current consumption, kWh/hL	8	10	13
Heat consumption, kWh/hL	30	40	50
Water consumption, hL/hL	4	6	8

Taxation. The varieties of beer are classified into various tax groups on the basis of their extract of original wort or alcohol content. The groups differ from country to country. There are different means of tax collection: (1) raw-material taxation, which is based on weight or volume of the brewing materials used; (2) intermediate product taxation, which is assessed according to the volume of the wort, and (3) finished product taxation, which is levied on sales beer.

7. Physiology and Toxicology

According to standard definitions, beer is classified as a food. In addition, it acts as a stimulant. The calorific content of beer as a nutrient may be calculated from its concentrations of protein, carbohydrate, and alcohol, as well as organic acids. A rough estimate in kJ/L can be obtained by multiplying the extract of original wort (in wt %) by a factor of 150. Hence beers with 10 – 14 % extract of original wort have an approximate calorific value of 1500 – 2100 kJ/L. From a nutritional point of view, the amino acids (on an average 140 mg/L) and vitamins (20 – 25 mg/L) are especially valuable. One liter of beer contains about 40 µg thiamine, 400 µg riboflavin, 7500 µg niacin, 650 µg pyridoxine, 1500 µg pantothenic acid, and 800 µg folic acid.

The consumption value of beer may be derived from its ingredients. Thirst quenching is accomplished by its high water content and its mineral concentration (total around 1000 mg/L, consisting of: sodium 20 – 30 mg/L, potassium 500 mg/L, calcium 30 mg/L, phosphorus 300 mg/L, and magnesium 100 mg/L). Carbon dioxide (4 – 8 g/L) and organic acids (up to 600 mg/L) have a relaxing, calming and, at the same time, stimulating effect. The dietetic effect of the beer is based mainly on its low sodium concentration. Because it also is free of fats, it will promote urination.

Pathogenic and toxic bacteria cannot survive in beer because of the presence of alcohol, carbon dioxide, bitter substances, and the low pH. A proper balance between alcohol and assimilable carbohydrates, proteins, phosphates, and vitamins results in a lower increase in blood alcohol levels by comparison with other alcoholic beverages. The toxicology of ethanol is treated elsewhere (→ Ethanol, Chap. 11.).

Benefits of Moderate Beer Consumption. Beer as a wholesome beverage has formed a staple part of human diet for thousands of years. When consumed moderately and regularly beer is not only enjoyable to drink, but also beneficial to health. A daily consumption of 60 – 80 g alcohol (corresponding to 1.5 to 2 L of beer) by a healthy, adult male, or 40 – 60 g alcohol by an adult woman is not harmful. These guidelines vary according to body weight, age and nutritional habits as well as physiological condition. Rules for reasonable beer consumption are given in [53], [54].

It has been shown in many studies throughout the world that moderate consumption of beer – in contrast to heavy drinking or abstention – is protective against cardiovascular diseases such as heart attack and some forms of stroke [55]. One explanation for this effect is that beer increases the level of "good HDL cholesterol" in the blood [56], another explanation is that alcohol reduces blood coagulation [57]. Beer is reported to protect against gallstone formation [58], diabetes [59], and even osteoporosis [60]. Hops contain active compounds which prevent calcium depletion of bones. Beer drinkers are protected against *Heliobacter pylori* bacteria [61], which cause stomach ulcers and may increase the risk of stomach cancer. Beer is also a source of soluble fiber (5 – 10 mg/L), originating from the cell walls of malted barley. A liter of beer contains on average 20 % of the recommended daily intake of fiber. Fibers do not only support a healthy bowel function, they also retard the digestion and adsorption of food, and lower cholesterol levels, which may help to reduce the risk of heart diseases [62].

Beer is also a source of antioxidants (200 – 600 mg phenolic carboxylic acids, flavonoids and tannoids per liter of beer), which show a cancerostatic activity [63–65]. Additional research has shown that the antioxidants present in beer are more readily available to the body than those from solid foods [66]. Furthermore, beer contains a large amount of dietetically valuable silicon as orthosilicate, its biologically available form. The silicon content of the human body has a direct effect on the mineralization of the bones and the density of the bone marrow. Beer contains 10 – 40 mg SiO_2 per liter, which is absorbed to more than 50 % by the human body. Thus beer is one of the most important dietetic silicon sources.

Harmful Substances. Numerous nutritional regulations require the amount of additives in beer to be kept to a minimum.

Heavy metals derived from raw materials are mostly removed during the malting and brewing process; beer is one of the beverages lowest in heavy metals (lead, 1 – 3 µg/kg; cadmium, 0.1 – 0.5 µg/kg; mercury, always less than 0.1 µg/kg). *Mycotoxins* and *insecticides* have

not been found in beer until now. *Fungicide* sprays, especially dithiocarbamates, are used in hop growing. The residues contained in the hops are metabolized during wort boiling to ethylenethiourea and propylenethiourea, which are only partially removed in the further brewing process and remain in the beer. The necessary sprayings could be reduced considerably by breeding spore-resistant types as well as by an early warning system. The concentrations of residue can also be cut to less than 5 mg/kg by allowing a time lapse of several weeks between the last spraying and the actual harvesting. Various hop extraction procedures also can lower the concentration of dithiocarbamates.

The World Health Organization (WHO) recommends a limit of *nitrates* of 50 mg per liter of drinking water. The nitrate in the wort originates mainly from water and hops. Nitrate is reduced to nitrite, which is poisonous to yeast. However, its concentration is much below the threshold considered critical by the WHO. The concentration of nitrate in beer corresponds to that of the brewing water. Nitrate can be most effectively removed from the water by anion exchange.

The concentration of highly carcinogenic *N*-nitrosodimethylamines is virtually negligible, because kilns are fired indirectly nowadays. With average values of less than 0.5 µg/kg, beer produced today is no longer significant as a potential source of nitrosoamines.

The byproducts formed during fermentation, such as higher alcohols, esters, and aldehydes, are of more importance for the aroma of the beer than for its wholesomeness. No connection can be found between the level of higher alcohols, fats, and aldehydes and the incidence of hangover.

Sulfur dioxide is a true fermentation byproduct. Bottom-fermented lager or pilsener contain 0 – 10 mg/kg, top-fermented beers 0 – 5 mg/kg, whereas strong beers may contain more than 10 mg/kg of the gas. The source cannot be traced back to the sulfur content of the malt, the hops, or the brewing water.

Histamine, a metabolite of histidine, occurs in beer in amounts of under 0.5 mg/kg, and has no toxic effect at this level. The *nucleic acid components* of beer originate from the raw materials. The yeast needs adenine and guanine for its growth and removes part of these substances during fermentation. The purines of the finished beer are broken down to uric acid in the human body, which can cause gout if the amount exceeds the solubility in blood. Bottom-fermented lager beers contain 70 – 130 mg purine per kilogram; in wheat beers the figure is around 80 mg/kg [67].

1. Introduction

Benzaldehyde is the simplest and industrially the most important aromatic aldehyde. It exists in nature, occurring in combined and uncombined forms in many plants. The best known natural source of benzaldehyde is amygdalin, in which it exists in a combined form as a glycoside and which is present in bitter almonds. The odor of bitter almonds arises from small amounts of free benzaldehyde formed by hydrolysis of the amygdalin. Owing to its occurrence in bitter almonds, the aldehyde was formerly referred to as "bitter almond oil." Benzaldehyde is also the main constituent of the essential oils obtained by pressing the kernels of peaches, cherries, apricots, and other fruits.

Benzaldehyde
[100–52–7]

In 1818 – 1819 VOGEL and MATRÈS reported for the first time, and independently of one another, that, in addition to hydrocyanic acid, a volatile oil could be obtained from bitter almonds. Later, in 1832, this oil was investigated by WÖHLER and LIEBIG; they determined its composition and recognized its relationship to benzoic acid and benzoyl chloride.

2. Physical Properties

Benzaldehyde, C_7H_6O, M_r 106.13, is a colorless and highly refractive liquid with an odor of bitter almonds. Like many other aromatic aldehydes, it is volatile in steam, *bp* 179 °C at 101.3 kPa, *mp* −56 °C, refractive index n_D^{20} 1.5450, density ϱ at 0 °C 1.063 g/cm^3, at 20 °C 1.046 g/cm^3, at 50 °C 1.018 g/cm^3, specific heat capacity c_p 1.676 J g^{-1} K^{-1} at 25 °C, heat of evaporation 371.0 J/g at 179 °C, standard heat of combustion 33.19 kJ/g, flash point 64.5 °C, autoignition temperature 190 °C, lower explosive limit 1.4 vol %. Vapor pressure versus temperature data for benzaldehyde are given in Table 1.

Benzaldehyde is miscible with many organic solvents; at 25 °C it is miscible with concentrated sulfuric acid, liquid carbon dioxide, liquid ammonia, methylamine, and diethylamine. The compositions of several binary azeotropic mixtures are given in Table 2. For further azeotropes, see [3]. Vapor – liquid equilibria data for binary mixtures of benzaldehyde with water or organic solvents will be found in [2]. One hundred milliliters of water dissolves 0.40 mL of benzaldehyde at 25 °C or 0.96 mL at 60 °C. Dynamic viscosity η 1.40×10^{-3} Pa · s at 25 °C, 1.11×10^{-3} Pa · s at 40 °C, surface tension σ 40.04×10^{-3} N/m at 20 °C, dipole moment μ (measured in liquid benzene) 2.92 D (9.74×10^{-30} C m), dielectric constant ε_r 17.7 at 25 °C.

2-Octanol	174.0	25.0
α-Terpinene	170.0	38.0
Diisoamyl ether	168.6	37.5

3. Chemical Properties

The chemical behavior of benzaldehyde and of its nuclear substitution derivatives corresponds largely to that of the aliphatic aldehydes (→ Aldehydes, Aliphatic and Araliphatic). But the reactivity of the carbonyl group of the aromatic aldehydes is somewhat less because the π electrons of this group are included in the resonance system of the aromatic ring. Thus benzaldehyde forms Schiff bases with amines, an oxime with hydroxylamine, a hydrazone with phenylhydrazine, and acetals with alcohols. It adds hydrogen cyanide, sodium bisulfite, and Grignard compounds. If benzaldehyde is reacted with hydrogen cyanide in the presence of ammonia and the aminonitrile formed as an intermediate is then saponified, DL-2-phenylglycine is formed (Strecker synthesis).

Benzaldehyde undergoes autoxidation in air. This process, the final product of which is benzoic acid, is accelerated by light and by the addition of peroxides or heavy-metal salts. It is retarded by antioxidants, such as phenolic compounds and diphenylamine. Nitric acid, chromium(VI) oxide, and other oxidizing agents also oxidize benzaldehyde to benzoic acid.

The reduction or hydrogenation of benzaldehyde leads to benzyl alcohol, dibenzyl ether, benzoin, 1,2-diphenylethane-1,2-diol, stilbene, toluene, methylcyclohexane, and other products, depending on the reaction conditions. Catalytic hydrogenation of benzaldehyde is used industrially to produce benzyl alcohol. Reduction with aluminum alcoholates (Meerwein-Ponndorf-Verley reduction) also gives benzyl alcohol. This reaction also permits the reduction of unsaturated aldehydes, such as cinnamaldehyde, to the corresponding alcohols, in which the olefinic double bonds are retained.

The reaction of benzaldehyde with ammonia and hydrogen in the presence of hydrogenation catalysts leads to benzylamine and is an important industrial process. The side-chain chlorination of benzaldehyde gives benzoyl chloride [4].

Like the aliphatic aldehydes, benzaldehyde participates in condensation reactions with a number of organic compounds possessing active hydrogen atoms. Some of these reactions are used for industrial purposes. The Claisen-Schmidt condensation of benzaldehyde with acetaldehyde in the presence of aqueous alkali leads to cinnamaldehyde.

The Perkin condensation of benzaldehyde with acetic anhydride in the presence of sodium acetate or potassium acetate as a condensing agent is carried out industrially in the production of cinnamic acid (→ Acetic Anhydride).

Cinnamic acid is also produced by Knoevenagel condensation of benzaldehyde with malonic acid in the presence of weakly basic catalysts, such as ammonia and amines.

In the Reformatsky reaction, ethyl cinnamate is obtained from benzaldehyde and ethyl bromoacetate in the presence of activated zinc.

The Cannizzaro reaction is typical of benzaldehyde and other aldehydes that have no α-hydrogen atoms. If concentrated sodium or potassium hydroxide is present, this reaction results in disproportionation to benzoic acid and benzyl alcohol.

Sodium benzylate and aluminum benzylate catalyze the Claisen-Tishchenko condensation of benzaldehyde, which leads to benzyl benzoate.

In comparison with their aliphatic analogues, benzaldehyde and other aromatic aldehydes have certain peculiar aspects in their reaction behavior. In the benzoin condensation, two molecules of benzaldehyde condense in the presence of cyanide to form the hydroxyketone benzoin. Thiazolium salts can be used as catalysts in place of cyanide [5].

The reactivity of benzaldehyde towards ammonia also differs from that of aliphatic aldehydes. Instead of stopping at the aldehyde – ammonia adduct, the reaction continues until 1-phenyl-*N,N′*-bis(phenylmethylene)-methanedi-amine (hydrobenzamide) is obtained.

Benzyl alcohol and benzoic acid, but no copper(I) oxide, are formed when benzaldehyde is treated with Fehling's solution. Aromatic aldehydes do not show the polymerization or formation of cyclic compounds that is observed with aliphatic aldehydes. The condensation of benzaldehyde with phenols, aromatic amines, and benzene leads to triphenylmethane derivatives. This reaction is exploited industrially in the production of Malachite Green dyes.

Electrophilic substitution of the aromatic nucleus (chlorination, nitration, sulfonation) occurs preferentially in the meta position.

4. Production

Benzaldehyde is produced principally by the hydrolysis of benzal chloride or the partial oxidation of toluene. There are various other manufacturing processes, but at present they have no industrial importance.

4.1. Hydrolysis of Benzal Chloride

The hydrolysis of benzal chloride, which is readily obtainable by side-chain chlorination of toluene, is among the oldest industrial processes for the production of benzaldehyde. It can be carried out either in an alkaline or in an acidic medium.

Hydrolysis under basic conditions can be carried out with calcium hydroxide, calcium carbonate, sodium hydrogencarbonate, or sodium carbonate. Excessive alkalinity increases the probability of side reactions. The preferred alkaline saponifying agent is sodium carbonate.

According to a fairly old process [6], benzal chloride is saponified with a small excess of 15 % sodium carbonate solution at 138 °C. The reactor is a carbon steel agitator vessel lined internally with Heresite (a phenolic resin) and having an agitator made of a copper – silicon alloy. The cooler, separator, and pumps are made of Karbate (a graphitic material). On completion of the saponification, the benzaldehyde is isolated from the reaction mixture by steam distillation and distilled in a stainless steel column at 2 – 3 kPa (20 – 30 mbar). The chlorine content of the distilled product is less than 0.01 %.

Instead of pure benzal chloride, a mixture of benzal chloride and benzotrichloride, as obtained industrially in the side-chain chlorination of toluene (→ Chlorinated Hydrocarbons), can be hydrolyzed. Under the reaction conditions, benzotrichloride is saponified to sodium benzoate, which remains in the aqueous alkaline

solution. It is converted separately to benzoic acid.

In a new continuous process [7], benzal chloride and the alkaline hydrolyzing agent are reacted as countercurrents in a flow reactor in an unreactive organic solvent (e.g., toluene, xylene). A temperature of 125 – 145 °C and a pressure of 1200 – 1800 kPa (12 – 18 bar) are maintained. In the extraction zone the dissolved aldehyde is extracted from the aqueous alkaline phase with an unreactive organic solvent flowing in the opposite direction. Water, likewise as a countercurrent, washes the solution of the crude benzaldehyde in the washing zone. The flow reactor, extraction zone, and washing zone are integrated in a special apparatus. The wash water and extract are returned to the hydrolysis zone in order to recover bezaldehyde (Fig. 1).

Figure 1. Hydrolysis of benzal chloride to benzaldehyde in a flow-through reactor [7]

Benzal chloride can also be converted into benzaldehyde by boiling with aqueous solutionsof hexamethylenetetramine [8]. Because benzyl chloride also reacts with hexamethylenetetramine to give benzaldehyde (Sommelet reaction), industrial mixtures of benzyl chloride and benzal chloride can be used to form benzaldehyde in this way.

The acid hydrolysis of benzal chloride is carried out in the presence of acids and with metal salts as catalysts. It gives very high yields of benzaldehyde (more than 90 %). Hydrogen chloride is formed simultaneously and is usually passed through an absorption unit to be recovered as concentrated hydrochloric acid.

The hydrolysis of benzal chloride was at one time commonly carried out in the presence of concentrated sulfuric acid. This process has the disadvantage that large amounts of dilute sulfuric acid are formed as a waste product. It can be used for the hydrolysis of certain substituted benzaldehydes that are difficult to saponify in other ways [9], [10]. Benzal chloride is also saponified in the presence of phosphoric acid or sulfonic acids [11], hydrochloric acid [12], and formic acid [13]. The reaction of benzal chloride with organic acids, such as acetic acid, in the presence of a tin(II) or tin(IV) chloride catalyst [14], gives benzaldehyde and the corresponding acid chloride.

R = alkyl, aryl, or cycloalkyl

The hydrolysis of benzal chloride is catalyzed by metal salts, preferably those of iron or zinc. Water should not accumulate in the reaction mixture during the reaction because it would reduce the activity of the catalyst [15], [16].

Two parts by weight of anhydrous zinc chloride are added to 700 parts by weight of distilled benzal chloride, stirred, and heated to 105 – 110 °C. The mixture is maintained at 100 – 120 °C, while 85 parts by weight of water are added at the rate at which water is consumed. After all the water has been added, the reaction temperature is maintained for one hour to ensure removal of the liberated hydrogen chloride [16]. The yield of crude benzaldehyde is 95 %, and the purity of the undistilled product is greater than 96.5 %.

The catalyst is not deactivated by a momentary excess of water if insoluble zinc catalysts, such as zinc phosphate or zinc laurate, are used [17]. Tin chlorides [18] and copper(II) chloride [19] are also catalytic. The hydrolysis of benzal chloride can be carried out batchwise or continuously, e.g., in a cascade consisting of several reactors.

A new continuous process [20] hydrolyzes benzal chloride in the vapor phase at temperatures of 100 – 300 °C. The reaction is catalyzed by activated carbon which has been treated with an acid, such as sulfuric acid, or impregnated with a metal chloride, such as iron(III) chloride, or with a sulfate, such as copper(II) sulfate. The benzaldehyde yield is 97 %. This process is particularly suitable for the hydrolysis of trifluoromethyl-substituted benzal chlorides, which are otherwise difficult to convert into the corresponding benzaldehydes. In a similar process, benzal chloride in the vapor phase at 300 °C is hydrolyzed to benzaldehyde using a silicon dioxide or aluminum oxide catalyst [21].

4.2. Oxidation of Toluene

The partial oxidation of toluene with oxygen to give benzaldehyde can be carried out in either the gas phase or the liquid phase. Benzaldehyde itself is easily further oxidized to benzoic acid and other products. Conditions must therefore be carefully chosen to favor only partial oxidation.

In the gas phase, the oxidation is carried out by passing toluene vapor, together with oxygen in a gaseous mixture such as air, through a catalyst bed in a tube-bundle or fluidized-bed reactor at a temperature of 250 – 650 °C. The reaction is highly exothermic, and effective cooling is necessary. It is advisable to dilute the mixture of toluene vapor and oxygen-containing gas with an unreactive gas, such as water vapor, nitrogen, or carbon dioxide. The benzaldehyde yield is favored by a low conversion rate (10 – 20 %) per pass, a short residence time (0.1 – 1.0 s), and a precise adjustment of the amount of oxygen. Even then, it is only 40 – 60 % of the theoretical yield based on toluene. The oxidation of toluene in the gas phase produces maleic anhydride, citraconic anhydride, phthalic anhydride, anthraquinone, cresol, acetic acid, and other compounds, in addition to substantial quantities of benzoic acid, carbon monoxide, and carbon dioxide [22]. The complete combustion of the toluene is retarded by applying high pressure [23] or by adding potassium sulfate or sodium fluoride to the catalyst [24].

Oxides of the elements of Groups V and VI of the periodic table are frequently used as catalysts, sometimes with other oxides. These oxide catalysts contain molybdenum and at least one additional element from among iron, nickel, cobalt, antimony, bismuth, vanadium, phosphorus, samarium, tantalum, tin, and chromium [25]. Some have palladium and phosphoric acid on activated carbon [26]. Others are mixed oxides of silver and transition metals, such as cobalt nickel, vanadium, platinum, or palladium [27], and one is a mixture of silver vanadate and iron vanadate [28].

Another process uses a mixed-oxide catalyst that has silicon dioxide as a carrier and contains uranium, copper, iron, phosphorus, tellurium, and lead, in addition to molybdenum [29]. At a toluene consumption of 35 – 50 % per pass, the selectivity of the benzaldehyde formation at reaction temperatures of 475 – 550 °C is 40 – 70 %. Catalysts based only on mixed oxides of molybdenum and uranium [30] require reaction temperatures of around 600 °C.

More important than gas-phase oxidation for the production of benzaldehyde is the oxidation of toluene in the liquid phase by oxygen in the form of air or other gaseous mixtures. This is carried out at 80 – 250 °C, preferably in the presence of cobalt, nickel, manganese, iron, or chromium compounds (alone or in combination) as catalysts. Lead compounds [31], ruthenium compounds [32], and thallium salts of organic acids [33] are also catalytic. A pressure at which the reaction medium remains liquid is chosen. Alkali, alkaline earth, and tertiary alkyl hypochlorites have been used as oxidation promoters [34] in place of the usual bromides. These promoters may cause corrosion, however.

Toluene can also be oxidized in an alcohol, e.g., methanol [35], an aliphatic aldehyde, e.g., acetaldehyde [36], or an acid, e.g., benzoic acid [37] or acetic acid [38]. Water can also be added to the reaction [39], but one process im-

proves the benzaldehyde selectivity by continuously removing the water formed in the oxidation reaction [40]. When a cobalt catalyst is used and conversion rates of up to about 25 % are achieved, this process gives aldehyde selectivities of 40 – 80 %.

In another process, the selectivity of the benzaldehyde formation is improved by liquid-phase oxidation of the toluene with oxygen in the presence of a phosphoric acid – palladium catalyst that also contains certain phosphorus, sulfur, or nitrogen modifiers [41]. For an oxygen consumption of 63 %, the yield of benzaldehyde is 41 %.

In the large-scale production of phenol by the Dow process and of ε-caprolactam by the Snia Viscosa process via the toluene – benzoic acid synthesis route (→ Benzoic Acid), considerable amounts of benzaldehyde are formed as a by-product. Because a large proportion of this byproduct is worked up into pure benzaldehyde, oxidation processes intended exclusively to produce benzaldehyde are seldom used industrially at the present time.

Even when catalytic liquid-phase oxidation of toluene is carried out for the express purpose of manufacturing benzaldehyde, substantial quantities of benzoic acid are formed. Depending on the reaction conditions, carbon dioxide, carbon monoxide, formaldehyde, formic acid, benzyl alcohol, benzyl hydroperoxide, biphenyl, methylbiphenyls, and other compounds are formed also as byproducts. The crude benzaldehyde is normally refined by distillation at reduced pressure in a stainless steel column.

Benzaldehyde produced by oxidation of toluene often contains small amounts of impurities that are difficult to remove by distillation and which discolor the product. To remove these impurities the benzaldehyde can be treated with aqueous alkali [42] or with water and a base metal such as zinc powder [43]. A color-stable product can be obtained by treatment with oxidizing agents, e.g., hydrogen peroxide, followed by distillation [44].

Those processes in which toluene is oxidized with other agents, such as manganese dioxide in sulfuric acid, sodium persulfate, chromium(VI) oxide in acetic anhydride, or chromyl chloride (Etard reaction), cause waste water disposal problems and are without industrial importance.

4.3. Other Production Processes

Other processes for the manufacture of benzaldehyde include the reaction of benzene with carbon monoxide [45], the oxidation or dehydrogenation of benzyl alcohol [46], and the ruthenium-catalyzed oxidation of styrene with periodate or hypochlorite [47]. Benzaldehyde can also be made by hydrolysis of mixtures of benzyl chloride and benzal chloride in dilute nitric acid, using vanadium pentoxide as catalyst [48], or in the presence of an aqueous solution of hexamethylenetetramine [8]. The reduction of benzoyl chloride [49] or methyl benzoate [50] can also be used. These processes have no industrial importance in the production of benzaldehyde and are more likely to be used to make certain nuclear-substituted derivatives.

5. Quality Specifications and Test Methods

Benzaldehyde is commercially available in two grades (Table 3). *Pure* benzaldehyde, which is suitable for most uses, accounts for more than 95 % of the amount sold. *Double-distilled* benzaldehyde is used mainly in the pharmaceutical, perfume, and flavor industries and must therefore be particularly pure and free from foreign odors.

Table 3. Purity specifications of benzaldehyde grades

Property	Industrial grade	
	Pure	Double-distilled
Assay, wt %	> 99.0	> 99.5
Benzoic acid, wt %	< 0.3	< 0.1
Water, wt %	< 0.3	< 0.1
Chlorine, wt %	< 0.02	< 0.007
Color (APHA)	< 20	< 20

Traces of chlorine compounds may be detectable in benzaldehyde obtained by the hydrolysis of benzal chloride, whereas benzaldehyde obtained by oxidation may contain byproducts formed in the oxidation of toluene. Benzaldehyde can now be produced, by hydrolysis of benzal chloride and by partial oxidation of toluene, to such a high standard of purity that it is suitable for all known applications.

A suitable quantitative determination method consists of reacting benzaldehyde with hydroxylamine hydrochloride and titrating the hydrochloric acid liberated. Gas chromatography in packed or capillary columns is becoming increasingly important, particularly in the determination of impurities. The pharmacopeias of the various countries should be consulted regarding the testing of benzaldehyde that is to be used for pharmaceutical purposes. United States Pharmacopeia XX includes tests for halogen compounds, hydrocyanic acid, and nitrobenzene.

6. Storage, Transportation, and Safety Regulations

Benzaldehyde is readily oxidized to benzoic acid in the presence of air and should therefore be stored under nitrogen. Tanks for benzaldehyde should be made of aluminum or stainless steel. Benzaldehyde can be transported in drums with baked enamel finishes or in tanks made of aluminum or stainless steel. The air content of containers used for shipping benzaldehyde must be minimized.

The transportation of benzaldehyde by rail and road is regulated by the provisions of Class 3, Figure 32c, of GGVE/RID and GGVS/ADR. The transportation of benzaldehyde by sea is not restricted by the IMDG Code. The labeling of benzaldehyde must comply with national regulations for dangerous substances or with Supplement I of the EEC Directive on the Packaging, Classification, and Labelling of Dangerous Substances, 6th Amendment (see Journal of the European Community no. L 360 of December 30, 1976).

Benzaldehyde belongs to Temperature Class T 4 (autoignition temperature 190 °C) and has a flash point of 64.5 °C. Electrical installations must be labeled accordingly. If it is finely divided in air, e.g., on cleaning cloths, sawdust, kieselguhr, or other materials with large surface areas, benzaldehyde shows a very strong self-heating tendency. Because of the relatively low autoignition temperature, there is a risk of spontaneous combustion under such circumstances.

7. Uses

Benzaldehyde is an important starting material for the manufacture of odorants and flavors. The compound is responsible for the odor of natural bitter almond oil and is incorporated directly in perfumes, soaps, foods, drinks, and other products. Substantial amounts are used in the production of derivatives that are also employed in the perfume and flavor industries. Examples of these derivatives are cinnamaldehyde, cinnamaldehyde dimethyl acetal, α-amylcinnamaldehyde, α-hexylcinnamaldehyde, dihydrocinnamaldehyde, cinnamyl alcohol, cinnamic acid, 4-phenyl-2-butanone (benzylacetone), β-bromostyrene, 2,2,2-trichloro-1-phenylethyl acetate, and benzyl benzoate.

Another application of benzaldehyde is the production of triphenylmethane dyes. For example, the leuco base of Malachite Green is obtained by condensation of benzaldehyde with dimethylaniline. The acridine dye benzoflavin is obtained from benzaldehyde and *m*-toluenediamine. In the pharmaceutical industry benzaldehyde is used as an intermediate in the manufacture of chloramphenicol, ephedrin, ampicillin, diphenylhydantoin, and other products.

Other important chemical intermediates obtained from benzaldehyde are benzoin, benzylamine, benzyl alcohol, mandelic acid, and 4-phenyl-3-buten-2-one (benzylideneacetone). Benzaldehyde is used in photochemistry, as a corrosion inhibitor and dyeing auxiliary, in the electroplating industry, and in the production of agricultural chemicals. The use of benzaldehyde in the extractive separation of isomeric amines has been proposed [51].

8. Derivatives

8.1. Chlorobenzaldehydes

2-Chlorobenzaldehyde [*89-98-5*], C_7H_5ClO, M_r 140.57, is a colorless to yellowish liquid with a penetrating odor and low solubility in water, *mp* 11.6 °C, *bp* 212 °C at 101.3 kPa, *bp* 91 – 92 °C at 2.0 kPa, density ϱ 1.248 g/cm^3 at 20 °C, refractive index n_D^{20} 1.5660, flash point 90 °C.

2-Chlorobenzaldehyde is produced mainly by chlorination of 2-chlorotoluene to form

2-chlorobenzal chloride, which is then subjected to acid hydrolysis. Metal salts, such as iron(III) chloride, are used as catalysts [52]. The hydrolysis can also be accomplished using formic acid without a catalyst [13]. 2-Chlorobenzaldehyde can also be produced by oxidation of 2-chlorobenzyl chloride with N-oxides of tertiary amines [53] or with dilute nitric acid [48]. 2-Chlorobenzaldehyde is considerably more resistant to oxidation than benzaldehyde. When it is heated with sodium sulfite solution under pressure, benzaldehyde-2-sulfonic acid forms.

3-Chlorobenzaldehyde [*587-04-2*], C_7H_5ClO, M_r 140.57, *mp* 17 °C, *bp* 213 – 214 °C at 101.3 kPa, *bp* 93 – 96 °C at 2.0 kPa, density ϱ 1.236 g/cm^3 at 20 °C, refractive index n_D^{20} 1.5641.

3-Chlorobenzaldehyde is formed in the nuclear chlorination of the benzaldehyde – aluminum chloride complex compound in the presence of chlorinated hydrocarbon solvents [54]. It can also be obtained from the diazonium salt of 3-aminobenzaldehyde by the Sandmeyer reaction.

4-Chlorobenzaldehyde [*104-88-1*], C_7H_5ClO M_r 140.57, is a colorless to yellowish crystalline mass with a penetrating odor and low solubility in water, *mp* 48 – 49 °C, *bp* 214.5 – 216.5 °C at 101.3 kPa, *bp* 98 °C at 1.87 kPa, flash point 88 °C.

4-Chlorobenzaldehyde is produced by the same methods as 2-chlorobenzaldehyde. Chlorobenzonitrile can be hydrogenated to form 4-chlorobenzaldehyde in the presence of an acid and a nickel catalyst that has been treated with a copper salt [55].

2,4-Dichlorobenzaldehyde [*874-42-0*], $C_7H_4Cl_2O$, M_r 175.02, *mp* 72 °C, *bp* 233 °C at 101.3 kPa, *bp* 105 – 106 °C at 2.0 kPa, flash point 135 °C.

2,4-Dichlorobenzaldehyde is produced by hydrolysis of 2,4-dichlorobenzal chloride with sulfuric acid.

2,6-Dichlorobenzaldehyde [*83-38-5*], $C_7H_4Cl_2O$, M_r 175.02, *mp* 71 – 72.5 °C.

2,6-Dichlorobenzaldehyde is formed by hydrolysis of 2,6-dichlorobenzal chloride with concentrated sulfuric acid. In aromatic sulfonic acids, hydrolysis can be catalyzed by zinc chloride, iron(III) chloride, or aluminum chloride [56]. 2,6-Dichlorobenzaldehyde has also been obtained by the oxidation of 2,6-dichlorotoluene with manganese dioxide and sulfuric acid. To separate the 2,6-dichlorobenzaldehyde from isomeric chlorine-containing benzaldehydes, the solution of the aldehyde mixture is extracted in an organic solvent with aqueous sodium bisulfite solution [57]. The 2,6-dichlorobenzaldehyde accumulates in the organic phase.

The chlorobenzaldehydes are important intermediates in the production of dyes, optical brighteners, agricultural chemicals, and pharmaceuticals.

8.2. Nitrobenzaldehydes

2-Nitrobenzaldehyde [*552-89-6*], $C_7H_5NO_3$, M_r 151.12, *mp* 42 – 44 °C, *bp* 153 °C at 3.07 kPa, highly volatile in steam.

The classical method for the preparation of 2-nitrobenzaldehyde begins with cinnamic acid, which is nitrated to form a mixture of 2-nitro- and 4-nitrocinnamic acid. The two isomers are separated by fractional crystallization after which the 2-nitrocinnamic acid is oxidized with potassium permanganate to form 2-nitrobenzaldehyde. Nitrobenzaldehyde can also be prepared by the oxidation of 2-nitrostyrene with ozone [58] or molecular oxygen [59]. Other processes begin with 2-nitrobenzyl bromide, which is oxidized to the aldehyde with dimethyl sulfoxide [60] or N-oxides of tertiary amines [53]. According to a similar process [61], 2-nitrobenzaldehyde can be obtained by the alkaline hydrolysis of 2-nitrobenzyl bromide followed by the oxidation of the intermediate 2-nitrobenzyl alcohol using nitric acid.

3-Nitrobenzaldehyde [*99-61-6*], $C_7H_5NO_3$, M_r 151.12, *mp* 56 – 58 °C, *bp* 164 °C at 3.07 kPa.

3-Nitrobenzaldehyde is obtained by the nitration of benzaldehyde with a mixture of concentrated sulfuric acid and nitric acid at 5 – 10 °C. In this process, up to 20 % of the 2-isomer is formed.

Warning: *A risk of explosion exists while the crude product is being distilled under reduced pressure* [62]. The two isomers can be separated by exploiting the difference in their reactions with bisulfite.

4-Nitrobenzaldehyde [*555-16-8*], $C_7H_5NO_3$, M_r 151.12, *mp* 107 °C, relatively involatile in steam.

4-Nitrobenzaldehyde can be obtained by the oxidation of 4-nitrotoluene with chromium (VI)oxide in glacial acetic acid. It can also be obtained by hydrolyzing 4-nitrobenzal bromide in 93 % sulfuric acid [63].

The nitrobenzaldehydes serve as intermediates in the production of dyes and pharmaceuticals.

8.3. Hydroxybenzaldehydes

2-Hydroxybenzaldehyde [*90-02-8*], salicylaldehyde, $C_7H_6O_2$, M_r 122.12, is a yellowish, oily liquid with an odor resembling that of bitter almonds; it is volatile in steam. It occurs naturally in cassia oil and in the essential oils of several plants of the genus *Spirea*, *mp* 1.6 °C, *bp* 196 °C at 101.3 kPa, *bp* 92 °C at 2.93 kPa, density ϱ 1.167 g/cm^3 at 20 °C, refractive index n_D^{20} 1.5718, dynamic viscosity η 2.50×10^{-3} Pa · s at 25 °C, surface tension σ 42×10^{-3} N/m at 25 °C, dipole moment μ (measured in liquid benzene) 9.54×10^{-30} C m (2.86 D) heat of combustion 27.29 kJ/g at 20 °C and constant pressure.

2-Hydroxybenzaldehyde is soluble in many organic solvents, in 20 % aqueous sodium carbonate, and in 10 % aqueous sodium hydroxide. At 86 °C, 1.7 g can be dissolved in 100 g of water. With iron(III) chloride, 2-hydroxybenzaldehyde gives an intense violet color. It forms yellow alkali salts through inner complexing.

The two most important processes for the manufacture of 2-hydroxybenzaldehyde begin with phenol. The best known process is based on the Reimer-Tiemann reaction, in which phenol is reacted with chloroform in the presence of an aqueous alkali. Moderate yields of 2-hydroxy- and 4-hydroxybenzaldehyde are obtained in a ratio of about 85 : 15. The use of aqueous methanol as a reaction medium [64] improves the yield, especially that of 4-hydroxybenzaldehyde. According to a modern variation [65] of the Reimer-Tiemann reaction, the process is carried out in the absence of water. An alkali-metal phenolate reacts with chloroform and a suspension of an alkali-metal hydroxide in an inert organic solvent.

One industrial process starts with phenol and forms 2-hydroxybenzyl alcohol (saligenin) by reacting triphenyl metaborate with formaldehyde [66]. The alcohol is catalytically oxidized in air to give 2-hydroxybenzaldehyde [67]. It is more economical to react phenol with formaldehyde in the presence of alkaline catalysts and in the absence of boric acid [68]. The yield is approximately 85 %. The ratio of 2-hydroxybenzyl alcohol to 4-hydroxybenzyl alcohol can be altered by varying the catalyst. The oxidation of the hydroxybenzyl alcohols is carried out in an aqueous solution with a platinum – lead – carbon catalyst and gives the corresponding hydroxybenzaldehydes in yields of more than 98 %.

Several other processes are based on side-chain chlorination of 2-cresol and saponification of the resulting dichloromethyl group to form the aldehyde group. The phenolic hydroxyl group is protected prior to chlorination by esterification with an inorganic or organic acid chloride, such as phosphorus oxychloride [69], phosgene [70], tetrachlorosilane [71], or acetyl chloride [72]. Hydrolysis splits the ester. 2-Hydroxybenzaldehyde can also be produced by electrolytic reduction of salicylic acid on a rotating amalgam cathode [73] and by catalytic reduction of a salicylic acid halide [74].

2-Hydroxybenzaldehyde is one of the most important derivatives of benzaldehyde. Estimated annual production worldwide is 4 – 6 kt. Because of its pleasant aromatic odor, 2- hydroxybenzaldehyde is used in perfumes and, on a large scale, as a starting material in the production of cumarin.

Its condensation products with amines have complex-forming properties and are used as additives, e.g., in petrochemistry. 2-Hydroxybenzaldehyde is also an intermediate for dyes, pharmaceuticals, plastics, photographic chemicals, agricultural chemicals, and electroplating chemicals.

3-Hydroxybenzaldehyde [*100-83-4*], $C_7H_6O_2$, M_r 122.12, *mp* 108 °C, *bp* 240 °C

at 101.3 kPa, heat of combustion 27.04 kJ/g at 20 °C and constant pressure, involatile in steam.

3-Hydroxybenzaldehyde can be produced by heating 3-chlorobenzaldehyde with aqueous potassium hydroxide under pressure at 250 °C [75] or by the reduction of 3-nitrobenzaldehyde to 3-aminobenzaldehyde and hydrolysis of the diazonium salt. It is used as an intermediate in producing dyes.

4-Hydroxybenzaldehyde [*123-08-0*], $C_7H_6O_2$, M_r 122.12, *mp* 117 °C, sublimes at 110 – 120 °C and 4 Pa, heat of combustion 27.18 kJ/g at 20 °C and constant pressure involatile in steam. At 18 °C, 0.81 g dissolves in 100 g of water.

4-Hydroxybenzaldehyde can be produced similarly to 2-hydroxy- and 3-hydroxybenzaldehyde. It can also be produced by treating benzaldehydes or acetalized benzaldehydes that have a benzyloxy residue in the 4-position with aqueous hydrogen halides [76]. The benzaldehyde derivatives used as starting materials are obtained by catalytic or electrochemical oxidation of *p*-benzyloxytoluene.

4-Hydroxybenzaldehyde is used in electroplating and is an important intermediate for making dyes, pharmaceuticals, textile auxiliaries, odorants, and agricultural chemicals.

8.4. Aminobenzaldehydes

2-Aminobenzaldehyde [*529-23-7*], C_7H_7NO, M_r 121.14, *mp* 39 – 40 °C, *bp* 80 – 85 °C at 270 Pa, low solubility in water.

2-Aminobenzaldehyde is obtained by the reduction of 2-nitrobenzaldehyde with iron(II) sulfate and ammonia or by catalytic hydrogenation. It is also formed in the hydrolysis of 2-dichloromethylphenyl isocyanate [77].

4-Aminobenzaldehyde [*556-18-3*], C_7H_7NO, M_r 121.14, *mp* 71 °C, soluble in water.

The preferred method for the production of 4-aminobenzaldehyde is the conversion of 4-nitrotoluene with sodium polysulfide. The reaction is carried out in an aprotic polar solvent, such as dimethylformamide [78].

The aminobenzaldehydes have a strong tendency to undergo self-condensation, in which they expel water. The aldehydes should therefore be isolated in the form of their stable N-acetyl compounds. They are used as intermediates in the production of dyes. 2-Aminobenzaldehyde is a starting material in the manufacture of quinoline derivatives [77].

8.5. Methylbenzaldehydes

2-Methylbenzaldehyde [*529-20-4*], C_8H_8O, M_r 120.15, liquid with the odor of bitter almonds, *bp* 199 – 200 °C at 101.3 kPa, *bp* 102 – 104 °C at 4.5 kPa, density ϱ 1.0328 at 20 °C, refractive index n_D^{20} 1.5462.

2-Methylbenzaldehyde can be produced by partial oxidation of *o*-xylene, e.g., in acetic acid with cobalt salts as catalysts and bromine compounds as promoters [79]. It can also be obtained from 2-methylbenzyl chloride by gas-phase oxidation at 350 – 450 °C in the presence of $Al_2O_3-V_2O_5$ catalysts [80]. In the Sommelet reaction, 2-methylbenzyl chloride reacts with hexamethylenetetramine to form 2-methylbenzaldehyde. This reaction can also use industrial chlorination mixtures containing small amounts of highly chlorinated products in addition to 2-methylbenzyl chloride and unreacted *o*-xylene [81].

3-Methylbenzaldehyde [*620-23-5*], C_8H_8O, M_r 120.15, liquid with the odor of bitter almonds, *bp* 200 °C at 101.3 kPa, *bp* 83 °C at 2.13 kPa, density ϱ 1.019 at 20 °C, refractive index n_D^{20} 1.5410.

3-Methylbenzaldehyde can be prepared similarly to 2-methylbenzaldehyde.

4-Methylbenzaldehyde [*104-87-0*], C_8H_8O, M_r 120.15, liquid with a pepper-like odor, *bp* 204 °C at 101.3 kPa, *bp* 85 – 86 °C at 2.0 kPa, density ϱ 1.019 at 20 °C, refractive index n_D^{20} 1.5454, dipole moment μ (in liquid benzene) 10.81×10^{-30} C m (3.24 D).

4-Methylbenzaldehyde is produced industrially by a modified Gattermann-Koch reaction. Toluene is reacted with carbon monoxide in the presence of hydrogen fluoride and tantalum(V) fluoride [82] or hydrogen fluoride and boron trifluoride [83]. It can also be produced similarly to 2-methylbenzaldehyde.

The modified Gattermann-Koch synthesis for the production of 4-methylbenzaldehyde [83] is the first of two stages in a process for the production of terephthalic acid from the inexpensive raw materials toluene and carbon monoxide [84].

The methylbenzaldehydes serve as intermediates (e.g., in the production of terephthalic acid) and are also used in the flavors industry.

9. Economic Aspects

The benzaldehyde production capacities of Western Europe, the United States, and Japan in 1983 were approximately 14 kt, 7 kt, and 3.5 kt, respectively. The corresponding production figures were approximately 12 kt, 4.5 kt, and 2 kt.

10. Toxicology

Benzaldehyde is used as a flavoring and fragrance in food, cosmetics, pharmaceuticals, and soap and is "generally regarded as safe" (GRAS) by the U.S. Food and Drug Administration. Benzaldehyde has industrial and agricultural applications, but no environmental or workplace exposure limits have been proposed.

Acute toxicity of benzaldehyde is moderate, with oral LD_{50} values reported to be 1.3 g/kg in rats and 1 g/kg in guinea pigs [85]. The probable lethal dose by mouth for a 70-kg human is estimated to be 50 mL. Subchronic oral administration to rodents produced no effects at daily doses of 400 mg/kg in rats and 300 – 600 mg/kg in mice. Higher doses caused necrotic and degenerative lesions in brain, kidney, and forestomach [86]. Tests for mutagenicity were negative in the Ames TA 100 *Salmonella* strain at concentrations of $0.1 - 10^3$ μg per plate [87]. No studies of carcinogenic, teratogenic, or reproductive effects have been reported.

Effects of toxic doses in acute and subchronic studies included depression, inactivity, tremors, seizures, and coma. Death may result from respiratory depression. Benzaldehyde has a weak local anesthetic effect and is mildly irritating to the eye and upper respiratory tract. Skin irritation is moderate, and allergic sensitivity may occur in some individuals [88].

Contact with eyes and skin should be avoided by use of gloves and protective clothing. Self-contained breathing apparatus should be used in poorly ventilated areas to prevent inhalation exposure.

1. Introduction

Benzene [*71-43-2*] is a single-ring, aromatic compound, C_6H_6, M_r 78.11; colorless, flammable liquid, *bp* 80.1 °C, *fp* 5.5 °C. The term benzene denotes the pure compound; benzol is still used to a small degree in some countries to represent the compound or a material having benzene as its main component. Benzine, on the other hand, is a low-boiling hydrocarbon mixture or naphtha, often nonaromatic in composition.

Benzene

Benzene is thermally stable but is chemically reactive and thus serves as a source for the production of many petrochemicals and hydrocarbon materials. Other chemicals derived from benzene are styrene, phenol, and cyclohexane; manufactured products include plastics, resins, and other intermediates used in insecticides, drugs, dyes, and detergents.

Benzene is an excellent solvent, but because of its high toxicity its use has decreased greatly, with less toxic materials taking its place. Benzene has a high octane rating and is an important component of gasolines.

Benzene was first isolated by M. FARADAY in 1825 [1]; he isolated "bicarburet of hydrogen" from experiments on the pyrolysis of whale oil and other materials. A. W. HOFMANN and C. MANSFIELD of the Royal College of Chemistry also were working on liquids obtained from pyrolysis of coal. They developed commercial processes for obtaining benzene and other aromatics from coal tar between 1840 and 1850.

Prior to World War II, benzene was obtained mostly from coal. Catalytic processes developed in the petroleum industry have made petroleum the main source for benzene and related aromatics.

2. Physical Properties

The structure of benzene was postulated by A. KEKULÉ in 1865 as a planar, six-carbon ring with alternating single and double bonds and with one hydrogen atom attached to each carbon atom. Thermodynamic and spectral studies indicate that this simple picture cannot explain the true nature of benzene or related molecules. For instance, when benzene is formed from cyclohexane, less energy (151 kJ, 36 kcal) is required than is needed for the formation of three double bonds. The NMR spectrum of benzene shows the protons at lower field than would be expected for simple vinylogous ones. Spacing

3. Chemical Properties

Benzene is the basic unit of the aromatic class of compounds. It is one of the largest volume organic chemicals, with the United States being the largest producer. Benzene is the source of a variety of organic chemicals, many of which are intermediates for the production of a host of commercial products. Benzene is thermally stable and its formation is kinetically and thermodynamically favored at temperatures $\geqq 500\,°C$. Therefore elevated temperatures are required for its thermal decomposition or for condensation or dehydrogenation reactions to occur. As an example, at ca. 650 °C in contact with iron, lead, or over other catalytic materials, such as vanadium, *condensation* reactions take place to form diphenyl and other polyaromatic compounds.

Benzene is quite stable to *oxidation*, but under severe conditions it is oxidized to water and carbon dioxide. With a deficiency of air or oxygen under oxidizing conditions, partial decomposition and deposition of soot occur. Oxidation with air or oxygen in the vapor phase at 350 – 450 °C over a V–Mo catalyst produces maleic anhydride in yields of 65 – 70 % [2]. The use of pure oxygen offers no advantage over air [3]. Phenol can be obtained in low yield from the high-temperature oxidation of benzene with air [4].

Substitution reactions of benzene are of primary importance. Depending on reaction conditions one or more of the hydrogen atoms in the benzene ring may be exchanged for nitro or sulfonic acid radicals, for amine or hydroxyl groups, or for atoms, such as chlorine or bromine. Products include phenol, nitrobenzene, chlorobenzene, benzenesulfonic acid, and others. For disubstituted benzene three isomers are possible:

Other important reactions of benzene involve *addition* and include alkylation and hydrogenation. These reactions generally take place at elevated temperature and pressure, sometimes requiring active catalysts. Ethylbenzene results from the alkylation of benzene with ethylene in the presence of a catalyst, such as aluminum chloride [5] (→ Ethylbenzene). The reaction is carried out at 40 – 100 °C, gauge pressure < 0.7 MPa. With less active catalysts higher temperature and pressure are employed [6].

The production of cumene by the vapor-phase catalytic alkylation of benzene with propene is another important primary addition reaction of benzene. The reaction takes place at 200 – 250 °C and gauge pressure of 2.7 – 4.2 MPa over active catalysts, such as phosphoric acid or kieselguhr, with yields of ca. 95 % [7].

Hydrogenation is also an addition reaction. One of the most important is the hydrogenation of benzene at elevated temperature and pressure to produce cyclohexane. The reaction may be carried out in the liquid phase [8] or in the vapor phase at higher temperatures.

The dehydrogenation of ethylbenzene to form styrene is an important commercial reaction (→ Styrene). High temperature is necessary both kinetically and thermodynamically for this endothermic reaction to proceed.

Most of the reactions discussed in this chapter are primary reactions of benzene. A myriad of reactions and products rely on benzene, either directly or indirectly, as their source. Many of these are shown schematically in Figure 1.

4. Raw Materials

Benzene and its homologues, such as toluene and xylenes, are found in crude oils but in such small amounts that physical separation and recovery generally has not been economically feasible. Table 7 shows the aromatic, naphthenic, and paraffinic contents of the petroleum and naphtha fractions of Saudi Arabian crudes and those of a similar fraction of a United Kingdom crude oil [9], [10]. Because the naphtha fractions represent < 15 % of the total respective crudes, the percentages of benzene, toluene, and xylene (BTX) are quite low. The benzene contents in these fractions are ≦ 50 % of the total aromatic contents shown. However, the naphthenes, which are generally potential benzene precursors, are usually present in larger amounts than the aromatics.

With heavier crudes the aromatic contents of the light naphtha fractions may be somewhat greater. In synthetic crudes, such as those derived from tar sands, an increased concentration of aromatics in the light naphtha fraction can

be expected. Such may not be the case, however. Table 8 contains an analysis of the C_5 – 150 °C naphtha fraction from a conventional crude and that of a synthetic naphtha derived from Athabasca tar sands [11]. The naphtha from the tar sands has lower contents of aromatics and naphthenes than does the fraction from the conventional crude. However, when the higher naphtha fractions are compared the synthetic crude has a considerably higher aromatic content (32 versus 19 %), although the naphthene content is lower in the synthetic crude. The higher aromatic content of the heavier fraction can be explained on the basis of dealkylation or of ring opening of the higher molecular mass aromatics in the bitumen.

∗ By GC analysis

The commercial sources of benzene, as well as toluene and xylenes in primary products, are coal and petroleum. Historically benzene production has been a byproduct of the carbonization of coal to produce coke for the steel industry. More recently petroleum has become the primary source as catalytic and thermal methods have been developed for producing aromatic or related compounds. These materials are used to improve gasoline quality or as feedstocks to produce petrochemicals. For example, catalytic reformates, pyrolysis gasoline, and alkylated aromatics, such as toluene and xylenes, provide sources for the commercial production of benzene. Production methods are discussed in Chapter 5.

5. Production

Until World War II, the coal industry supplied most of the commercial benzene in the United States and other countries. The pyrolysis of coal to yield metallurgical coke produced byproduct gas and aromatic liquid from which benzene and related aromatics were recovered by extraction and distillation. The small concentrations of benzene, toluene, xylene, etc., in crude oil fractions made this potential source noneconomic.

New processes discovered and commercialized in the petroleum industry during the 1930s and 1940s and the greatly increased demand for aromatics over this period changed the situation. Petroleum became more important as a raw material for the production of benzene and its homologues in the United States. Today, petroleum is the main source of the BTX aromatics – benzene, toluene, and xylenes.

During the 1930s catalytic cracking made its debut, first as fixed-bed processing and later as moving-bed processes. Cracked light naphthas contained a considerable aromatic content in contrast to the low concentrations found in virgin light naphthas. During this period catalytic reforming of virgin naphthas also became a reality. Aromatics, such as benzene, were made by dehydrogenation of cyclohexane or by isomerization and dehydrogenation of methylcyclopentane. *n*-Hexane was converted to benzene in smaller yields and under modified reaction conditions.

5.1. Production from Coal

Light oils from the carbonization or coking of coal have long been sources of BTX (→ Coal Pyrolysis). The carbonization process also produces a C_5 and lighter fraction and a heavier coal tar fraction. In the coking of coal, the yields and composition of the light oils depend on the type of coal being processed and on the carbonization temperature. *Low-temperature coking* was formerly employed to produce gas for heating and lighting. *Low-temperature* (< 700 °C) *carbonization* was important, especially in industrialized Europe before the advent of natural gas, petroleum, and other forms of energy. The benzene content of the BTX is lower in this case than when coking is carried out at a higher temperature. Low carbonization temperatures produce a rather low-density, clean burning coke.

High-temperature carbonization was developed to produce a hard coke for use in blast furnaces of the steel industry. *High-temperature*

coking is done at $\geqq 900\,°C$. A typical composition of light oils produced in coke-oven operation is (vol%): benzene (63), toluene (13), xylenes (8), higher aromatics (10), nonaromatics (6) [8].

Typical yields of liquid products obtained from slot-type coke-oven operations are 11 – 15 L of light oil and 30 – 38 L of coal tar pitch per ton of coal charged [12]. About 1 % of ammonium sulfate and around 2800 L of coke-oven gas per ton of coke are produced. Coke and coke breeze yields are about 75 %.

Whereas the benzene content of light oils derived from coke-oven operation is $\geqq 65$ wt%, the concentration is much lower (ca. 45 %) in light oils derived from vertical retort operations. The typical, crude BTX material from coke oven operation mentioned previously contains considerable amounts of higher boiling aromatic and nonaromatic materials. These include around 5 % of material boiling below benzene, which may be designated C_5 and lighter. These compounds may include aliphatics, simple olefins, and unsaturates, such as cyclopentadiene. Carbon disulfide, another low-boiling impurity, may be present at ca. 0.5 %. It as well as thiophenes must be removed (see Chap. 6).

Figure 2. Recovery of light oil from coke-oven gas
a) Cooler and removal of residual tars and impurities; b) Light oil scrubber; c) Light oil stripper; d) Separation and cooling; e) Separator

The overhead gas and the liquids from the coke-oven operation pass through a separation system. The gas and BTX fractions are separated from the coal tars and pass overhead to a recovery system where the C_5 and lighter fraction compounds are separated overhead from the BTX. The BTX fraction is recovered from the C_5 and lighter gas by countercurrent absorption using a high-boiling (generally 300 – 400 °C) petroleum fraction. Subsequent recovery of the BTX from the absorbent oil is accomplished by steam stripping. The BTX overhead products are condensed and separated from the water. One version of the process is covered in a U.S. patent issued to Bethlehem Steel [13]. A simplified flow sheet common to several processes is shown in Figure 2.

Separation and Refining of BTX Fractions. The crude BTX as obtained from the coke-oven recovery system must be refined to remove impurities so that the different BTX components meet purity specifications. Distillation removes C_5 and lighter hydrocarbons, carbon disulfide, and cyclopentadiene. Treatment with sulfuric acid removes thiophene and other sulfur compounds. Further purification by hydrotreating removes unsaturates, sulfur compounds, and nitrogen impurities. Hydrodealkylation reactions may accompany the hydrotreating process. Finally, recovery of the desired aromatics may be accomplished by solvent extraction and close fractionation to separate the individual aromatic components.

Individual processes for these different operations are being used. These include several combination processes that have been developed where the different chemical reactions are included in the overall process. The patent literature contains many references to combination processes designed to process coke-oven light oils into high-purity benzene or into high-quality BTX components. Modifications of these processes are used for the recovery of naphthalene from the crude BTX [14], [15].

One combination process, the *Houdry-Litol process,* has been in commercial operation since 1964. In 1981 there were six commercial installations operating in various countries [16], [17]. In this process a prefractionation removes the C_5 and lighter fraction, and the bottoms containing C_9 and heavier hydrocarbons. The BTX cut is passed to a pretreat catalytic reactor. Reactive unsaturates, e.g., cyclopentadienes and styrene, are selectively hydrogenated over a catalyst, such as cobalt molybdate on alumina. Hydrogenation of some sulfur compounds also occurs. Temperatures of ca. 250 – 350 °C and pressures of 5 – 7.5 MPa are used. More active catalysts allow lower reaction temperatures.

A second reaction system operates at $\geqq 600\,^{\circ}C$ using a chromia – alumina catalyst. The reactions that take place include:

1) Desulfurization

$$CS_2 + 4\,H_2 \longrightarrow CH_4 + 2\,H_2S$$

2) Hydrocracking

$$C_6H_{12} + 3\,H_2 \longrightarrow 3\,C_2H_6$$

3) Aromatization

$$C_6H_{12} \longrightarrow C_6H_6 + 3\,H_2$$

or

$$C_6H_{14} \longrightarrow C_6H_6 + 4\,H_2$$

4) Hydrodealkylation

$$C_6H_5CH_3 + H_2 \longrightarrow C_6H_6 + CH_4$$

5) Dehydrogenation of naphthenes

$$C_6H_{12} \longrightarrow C_6H_6 + 3\,H_2$$

A modified Litol process is more adaptable for complicated coke-oven aromatic materials [17]. In the Litol and related processes the readily polymerizable unsaturates should not exceed 2 – 3 % and nonaromatics should be limited to a similar amount. In the hydrodealkylation step about 50 % of the toluene and 75 % of the xylenes are dealkylated to benzene. After treatment of the Litol reactor effluent with clay, benzene is recovered and the remaining toluene separated by fractionation.

A small amount of benzene is available from the distillation of coke oven tars or tars from other coal carbonization processes. The low-boiling fractions containing BTX materials are treated with base to remove tar acids. Purification by hydrodealkylation produces benzene. Generally, however, the light oil fraction is 1.0 % or less of the coal tar [18]. Hence, this source is not of major importance in the production of benzene. Coal tars are more important as sources of pitches and of naphthalene, anthracene, or other condensed aromatic materials.

5.2. Production from Petroleum

Catalytic cracking and catalytic reforming of petroleum, adventing during the late 1930s and the 1940s, became a new source for the production of benzene, toluene, xylenes, and higher aromatics. Petroleum rather than coal began to emerge as the source of BTX materials, especially in the United States. In the United Kingdom and Europe the transition from coal to petroleum came around 1960.

Toluene was in great demand during World War II for the production of the explosive, trinitrotoluene (TNT). However, production of toluene from virgin naphthas and later from catalytically cracked and catalytically reformed naphthas was expensive. One of the early catalytic cracking processes was developed by Houdry Corp. [19], [20]. The silica – alumina catalyst used in this process was deposited in several fixed catalyst beds. The catalyst was regenerated frequently with air to burn deposited coke. Another process developed by Mobil Oil used a moving-bed silica – alumina catalyst [21]. The third type of process, developed by Exxon [22] and others, is known as the fluid process (FCC), and is now used exclusively.

Although the catalytic cracking processes were developed primarily for increasing the yield and octane rating of the motor fuels produced, the aromatic content of the gasolines was quite high [23] and so these processes provided a source for petrochemical benzene.

5.2.1. Benzene from Reformate

Catalytic reforming provided another petroleum source for BTX aromatics. Installation of these processes took place in the 1940s and early 1950s, at a time when the demand for benzene was expanding rapidly because of development of processes requiring it to manufacture resins, detergents, synthetic fibers, and other chemicals. Chemical reactions involved in reforming include dehydrogenation of naphthenes to aromatics, or isomerization of alkylnaphthenes followed by dehydrogenation. Likewise, paraffins may be dehydrocyclized to aromatics. The reaction is quite slow and process conditions must be adjusted to make it economic. A small amount of dealkylation of alkylated aromatics may occur.

Early catalytic reforming units used base-metal catalysts, generally molybdena on activated alumina. These processes operated on a short process cycle with frequent catalyst regeneration. The hydroforming process [24] operated at elevated temperatures of about 520 °C and at pressures of 2.5 – 7 MPa with hydrogen recycle. This process converted naphtha fractions into high-octane gasolines. The 10 % molybdena on alumina catalyst required regeneration every 8 – 16 h. The process consisted of two parallel systems of two reactors in series. One pair of reactors could be in use while the catalyst in the other pair was being regenerated. Later catalytic reforming processes using base-metal catalysts employed either moving catalyst beds with the catalyst in granular form or used fluidized beds with a finely divided catalyst of small particle size.

Various catalytic processes using platinum on alumina and platinum with modifiers on alumina have been developed [25]. These methods may have process cycles as long as six months or much shorter cycles, depending on the feedstock, the process conditions, and the severity of operation. Pretreatment of the naphtha feedstock by catalytic hydrotreating is required to remove sulfur compounds. Commercial catalytic reforming processes include: catalytic reforming (Institut Français du Pétrole), magnaforming (Engelhard Industries), platforming (UOP), powerforming (Exxon Research & Engineering), rheniforming (Chevron Research Co.), and ultraforming (Standard Oil of Indiana).

Operating conditions cover a considerable range: temperatures vary from 425 to 525 °C and gauge pressures from 0.7 to 3.5 MPa. Hydrogen recycle rates depend on whether long process cycles or whether frequent or continuous catalyst regeneration is employed. Naphtha feedstocks vary but generally are in the gasoline boiling range. Narrower boiling range stocks may be used if aromatics are the desired end products. Regenerative-type products generally allow lower pressures, less recycle hydrogen, and higher severity operation. Naphthene conversions approach 100 %. Cyclization of paraffins is much lower. For example, for benzene production from C_6 and higher stocks, methylcyclopentane is isomerized to cyclohexane and dehydrogenated to benzene. Conversion of *n*-hexane to benzene is limited.

Catalytic reformer units may be operated at relatively high pressures with a series of fixed-bed reactors, the catalyst being regenerated at defined intervals. Units designed for higher conversion operate at lower pressure with more frequent catalyst regeneration. Shorter cycles, swing reactors, or continuous regeneration are employed. The version of platforming [26] shown in Figure 3 employs continuous catalyst regeneration. Another design developed by Standard Oil of Indiana uses a swing reactor in which the fixed-bed catalyst in one reactor is regenerated and brought back onstream, with the catalysts in each of the remaining reactors being regenerated in rotation. Gauge pressures of ca. 0.7 – 2.4 MPa are employed in the different processes. For gasoline production, naphthas used have boiling ranges of around 80 – 210 °C. If reforming is carried out for the production of aromatic charge stocks, the composition and boiling range of the naphtha may be altered. The reformate may have RON clear octane rating as high as 100 and may contain up to 70 vol% aromatics. Typical compositions of reformate at different levels of reforming severity are shown in Table 9.

Over the years, the process has been made more effective. Reforming catalysts have been modified. Water in small amounts was found to enhance benzene yields with certain catalysts when producing BTX [27]. Higher xylene yields have resulted from operating at increased space velocities.

5.2.2. Aromatics from Pyrolysis Gasoline

Pyrolysis gasoline (dripolene), produced as a byproduct from the high-temperature, short-residence time cracking of paraffin gases, naphthas, gas oils, or other hydrocarbons used to produce ethylene, is another excellent source for BTX. The quantity of byproduct pyrolysis gasoline produced is a function of feedstock and operating conditions [28], [29]. Although the amount may be small with ethane and other gaseous paraffins as the ethylene charge stocks, it increases when heavier charge stocks are used. On a once-through basis, amounts may be 20 % in the high-severity cracking of a medium range naphtha. As the boiling point of the feed increases, a larger yield of toluene and xylene, rel-

∗ Including styrene

ative to that of benzene, is produced. Table 10 shows a typical composition of pyrolysis gasoline [30]. The BTX content of the pyrolysis gasoline is > 60 %. Because of the high temperature necessary for ethylene production, the pyrolysis gasoline contains other unsaturates and diolefins. Diolefin content is typically $\geqq 5$ % as is the total content of cyclic olefins and cyclic diolefins [31].

Table 11 gives an analysis of pyrolysis gasolines by carbon groups [30], [32]. Pyrolysis gasoline is quite unstable because of the appreciable amount of diolefinic material. Lower boiling diolefins may be removed by distillation although their tendencies to polymerize and depolymerize may cause difficulties. Therefore a two-stage hydrotreating is generally employed. In the first stage a mild selective hydrotreating converts diolefins to olefins. If this gasoline is to be used as a fuel, further treatment may not be necessary. However, if the gasoline is a source of aromatics, a second stage is employed to saturate olefins and to remove residual sulfur.

5.3. Methods of Increasing Production

Depending on demand, benzene production from other aromatic compounds can be increased, particularly from the BTX fractions obtained from catalytic reformate, pyrolysis gasoline, or light oils from coal carbonization. Among the methods used are hydrodealkylation, disproportionation, or combination processes.

5.3.1. Hydrodealkylation

Hydrodealkylation of alkyl aromatics is a source of benzene. Toluene is the usual charge stock, although higher alkylated aromatics may be used:

$$C_6H_5CH_3 + H_2 \xrightarrow{\text{Heat}} C_6H_6 + CH_4$$

With more highly alkylated benzenes, the reaction proceeds stepwise:

$$C_6H_4(CH_3)_2 + H_2 \xrightarrow{-CH_4} C_6H_5CH_3 \xrightarrow{H_2} C_6H_6 + CH_4$$

Other alkylbenzenes, such as ethyl- and propylbenzene, dealkylate in a single step and form the corresponding alkanes. Both catalytic and thermal processes are used. The catalytic processes, e.g., Detol (Air Products & Chemicals) [33] and Hydeal (UOP) [34], operate at 575 – 650 °C and 2.5 – 6 MPa. The temperature of this exothermic reaction is controlled by recycling cold hydrogen.

Thermal dealkylation processes, such as HDA (Arco and Hydrocarbon Research) and THD (Gulf Oil), operate at higher temperatures than the catalytic, but yields and reaction systems are similar in both types. For a comparison of the different processes see [35].

The amount of toluene in BTX from catalytic reformate is greater than that of benzene. Whether or not hydrodealkylation is used is related directly to the demand and price of benzene relative to toluene. If the relative demand for the two products changes, the dealkylation units may be placed on standby.

Detol Process [33], [36]. This catalytic dealkylation process is illustrated in Figure 4. Benzene is produced from a feed consisting of toluene or mixtures of toluene and other alkylated benzenes. The alkylated aromatics and hydrogen pass at elevated temperature and pressure over a fixed-bed dealkylation catalyst, generally dispersed in more than one reactor in series. Heat exchangers cool the reactor products and condense benzene, unreacted toluene, and the heavier unreacted alkylated benzenes. A high-pressure flash drum separates recycle hydrogen and product gas. The gas is split into streams for fuel gas, for hydrogen purification if needed, and for recycle hydrogen.

The product gas from the flash drum is condensed and the liquid pumped to a stabilizer, where remaining gas and low-boiling hydrocarbons are driven off and utilized as fuel gas. The bottoms from the stabilizer are clay treated and passed to a column where the benzene is distilled overhead. Unreacted toluene and heavier aromatics are recycled. The benzene produced in yields of around 99 mol% is highly pure, typically 99.95 %, with a freezing point of 5.45 °C. Minor side reactions, such as hydrocracking and hydrogenation, occur and produce small amounts of light hydrocarbons and also eliminate sulfur compounds (e.g., thiophene). Catalyst cycle life in these dealkylation processes is long, as it is in other high-pressure reactions carried out in the presence of hydrogen. As of 1981 twelve commercial Detol plants had been licensed.

Hydeal Process [34], [37]. This process was developed jointly by Ashland Oil and UOP. The process is similar to the Detol one described previously. Toluene alone or in mixtures containing xylenes and other alkylated benzenes is

charged to the catalytic reactor, which contains a chromia – alumina catalyst. Hydrogen is added along with the alkyl aromatics. Nitration-grade benzene is obtained in yields of ca. 98 mol%. Unreacted aromatic charge material from the once-through operation is recycled to obtain practically complete conversion. The process is also used to hydrodealkylate alkylnaphthalenes.

Figure 5. HDA process

HDA Process [38], [39]. This process, developed by Arco and Hydrocarbon Research, operates at 600 – 660 °C and at gauge pressures of 3.45 – 6.9 MPa (see Fig. 5). Operation is similar to that of the catalytic processes, with benzene yields of 99 mol%. The small amounts of diphenyls formed are recycled and a low-equilibrium concentration is maintained, permitting high benzene yields.

THD Process [40]. This Gulf process is similar to the other thermal processes.

MHC Process [41], [42]. Mitsubishi Petrochemical Co. has described a thermal dealkylation process known as MHC. Methods are emphasized for controlling condensation reactions and coke formation. The following advantages are claimed for the MHC process. Feedstocks containing up to 30 % of nonaromatics can be handled without resorting to aromatic extraction and fractional distillation steps. The process will operate on low-purity hydrogen, thus reducing

the amount of makeup hydrogen required. Benzene of 99.95 % purity is readily achieved. Figure 6 is a flow sheet of the MHC process.

5.3.2. Disproportionation

Processes have been developed to disproportionate or transalkylate alkylated aromatics to produce benzene and alkylated benzenes. For example, the Tatoray process (UOP and Toray Industries, see Fig. 7) [43–45] produces benzene and equilibrium xylenes from toluene or from a mixture of toluene and C_9 aromatics:

$$2\,C_6H_5CH_3 \longrightarrow C_6H_6 + C_6H_4(CH_3)_2$$

$$C_6H_5CH_3 + C_6H_3(CH_3)_3 \longrightarrow 2\,C_6H_4(CH_3)_2$$

The reaction proceeds with a high H_2 recycle rate over a noble-metal or rare-earth catalyst. Operating conditions are 350 – 525 °C and 1 – 5 MPa.

Benzene of high purity (*fp* 5.45 °C) and xylenes containing $< 10^{-9}$ parts of saturated hydrocarbons are produced. When the feedstock is limited to C_9 and C_{10} aromatics, a mixture of benzene, toluene, and xylenes results. Typical yields with toluene as the charge are about 97 %. Yields for both a pure toluene feed and a mixed feed of toluene and C_9 + aromatics are shown in Table 12.

Four commercial units were in operation in 1981 and others were being designed or built.

5.3.3. Combination Dealkylation Processes

Several combination dealkylation processes have been developed for producing benzene from impure BTX feedstocks. The Houdry Division of Air Products developed the *Pyrotol process* [46], [47] by a combination of hydrogenation and dealkylation (Fig. 8).

Essentially the process involves fractionation of the feed to remove C_5 minus and C_9 plus material from the crude BTX. The $C_6 - C_8$ is vaporized and passes to a catalytic pretreat reactor for selective hydrogenation of diolefins, cyclic diolefins, and styrene. The effluent from the pretreat reactor is subsequently charged to the Pyrotol reactors, where aromatics are dealkylated to benzene. Other reactions include desulfurization and hydrocracking of nonaromatics. Unreacted toluene and heavier aromatics from the first pass are recycled. The benzene product contains less than 0.5 ppm of thiophene and has a freezing point of at least 5.47 °C. Table 13 contains typical yield data. As of 1982 thirteen plants had been licensed.

A somewhat similar process was developed by the Houdry Division of Air Products and by Bethlehem Steel. The *Litol process* has been in operation in the United States and other countries. It produces pure benzene from aromatic light oil obtained from coal carbonization [48]. This process, as the Pyrotol process, utilizes two catalytic reaction stages. After prefractionation of the raw light oil to remove C_5 and lighter fractions overhead and C_9 and heavier as bottoms, the $C_6 - C_8$ fraction is vaporized.

At the first stage diolefins and styrene are hydrogenated. The effluent then contacts the Litol chromia – alumina catalyst at 500 – 600 °C, where desulfurization, hydrocracking, and dealkylation occur. Benzene purity of 99.97 % with freezing point of 5.5 °C and a thiophene content of less than 0.5 ppm are typical.

In 1968 a modified Litol process was developed [49]. This modified process is designed to include a heavier fraction of the light oil, mostly C_9s and heavier, along with the secondary light oil ($C_6 - C_8$) normally used in the process. The lighter fraction typically contains around 70 % benzene, 20 % toluene, and 6 % xylenes and ethylbenzene. The primary, or heavier fraction of the light oil, has a typical boiling range of 180 – 260 °C and is composed mainly of C_9 and heavier aromatics. Pilot plant operation indicates that a 50 – 50 mixture of the lower and higher boiling range light oils can be processed.

Mitsubishi Petrochemical Co. described a process [50] for producing benzene from pyrolysis gasoline by a combination method similar to those discussed previously. After a two-stage hydrogenation a solvent was used to extract the aromatics. Alternatively, the hydrogenated material was reacted in Mitsubishi's MHC process [42], [51], [52]. Advantages of the process are low-temperature liquid-phase operation of the first stage with no need for hydrogenated product recycling, and a reactor design incorporating an improved method for controlling temperature of the exothermic reactions.

Mobil Chemical Co. has developed an aromatics processing catalyst and a process for the liquid-phase disproportionation of toluene to form benzene and xylenes (Fig. 9) [53], [54]. This *low-temperature – disproportionation process* (LTD) employs a zeolite-based catalyst of high activity which permits the reaction to proceed at temperatures as low as 260 °C; gauge pressure is 4.5 MPa. No hydrogen recycle is required in this liquid-phase process. An hourly mass-space velocity is standard. A catalyst life of 1.5 years is claimed with infrequent regenerations. With fresh or regenerated catalyst the initial reactor temperature is 260 °C. As the catalyst slowly deactivates, the temperature is raised in increments to 315 °C; then the catalyst is regenerated by burning accumulated coke.

After cooling the reactor effluent passes to three distillation columns arranged in series. In the first column non-aromatics plus a small amount of benzene are taken overhead. This benzene may be recovered by extraction if deemed necessary. Benzene is taken overhead as product in the second column and toluene is distilled overhead for recycle in the third column. Xylenes and heavier aromatics are withdrawn as bottoms from this last column. The C_9 + aromatics may be recycled. Toluene conversion on a once-through basis is around 45 % and the balance is recycled to extinction. Table 14 contains

5.3.4. Benzene from Other Sources

The development of energy from solid fuels, such as coal, oil shale, and tar sands, may provide other potential sources for the production of benzene [55]. For example, if coal is developed as a source of liquid fuels, it has potential for benzene production [56–59]. Some of the processes being investigated include noncatalytic liquefaction, SRC-I and the related SRC-II. Others are COED, Exxon Donar Solvent, indirect liquefaction via the Fischer-Tropsch method, and the LCFFC catalytic process by Lummus. Coal gasification also may yield naphthas that can serve as charge material for benzene production.

Production of liquid fuels from coal has been known since 1911 when Bergius hydrogenated coal. Hydrogenation and Fischer-Tropsch plants were a source of liquid fuels in Germany during the 1940s. Two commercial processes for the production of liquid fuels from coal are the Sasol plants in South Africa [55] and the Mobil methanol-to-gasoline plant now under construction in New Zealand [60–62]. A third commercial process, using tar sands as raw material for the production of liquid fuels, has been described

Table 14. LTD fresh feed and product composition, wt % [54]

Component	Feed	Product
Nonaromatics		0.2
Benzene		43.8
Toluene	99.7	0.1
Ethylbenzene	0.1	0.2
p-Xylene	0.1	12.2
m-Xylene	0.1	27.3
o-Xylene		11.5
Trimethylbenzenes		4.0
Other C_9 + aromatics		0.7
Total	100.0	100.0

[55]. Other potential sources of liquid fuels include shale oil developments, biomass conversion, and the production of hydrocarbon liquid fuels from ethanol.

The yields of chemical feedstocks and gasolines from coal conversion depend on the process or combination of processes employed. For example, a BTX yield of 2.5 %, based on coal charged, was projected using a combination of processing including the Fischer-Tropsch route [63]. Hydroliquefaction followed by processing of the naphtha produced can increase BTX. Another study indicates a liquid yield of ca. 50 %. Distillate yields from other liquefaction processes, such as SRC-II and H-coal, are ca. 50 %, with an aromatics content of ca. 25 %. Fischer-Tropsch gasolines generally have a lower aromatic content than those from liquefaction processes. Unless secondary aromatization is carried out, the benzene content of distillates from Fischer Tropsch processes is generally lower than that found in petroleum derived gasolines.

Thus carbon-containing materials, such as coal, tar sands, and oil shale, are potential raw materials for benzene production. However, their commercial use is not imminent as long as petroleum is in ample supply at a reasonable price. Exceptions are light oils from coal carbonization and possibly coal conversion processes, such as Sasol and others in operation or under construction.

6. Separation and Purification

The separation and purification of benzene from crude BTX fractions or the separation of the different BTX components is accomplished by different methods and processes, such as those outlined in this chapter. The BTX fractions from catalytic reforming are the easiest to handle in that most of the objectionable impurities have been removed during reforming. Light oils from coal carbonization and pyrolysis gasoline from high-temperature manufacture of ethylene need additional treatment to remove impurities, such as dienes, olefins, and sulfur compounds, as well as small amounts of nitrogen and oxygen before proceeding with the recovery and separation of the aromatic components.

6.1. Removal of Dienes, Olefins, and Sulfur Compounds

Pyrolysis gasolines need pretreatment because of appreciable diene content. A two-stage hydrotreating process is generally employed. The dienes are hydrogenated to olefins in a mild first stage. In a second stage olefins are saturated and sulfur compounds are removed under more severe conditions. However, conditions are mild enough to avoid saturation of aromatics. Both base-metal and noble-metal catalysts are employed in diolefin removal. Nickel molybdate and cobalt molybdate generally are used in olefin and sulfur removal. Temperatures of 30 – 175 °C and pressures of 2 – 6 MPa are typical for diolefin operation. Noble-metal catalysts generally require lower temperatures than base-metal catalysts. Space velocities range from 2 to 10 vol of feed per volume of catalyst per hour, with higher values permitted with noble-metal catalysts.

Shell Development Co. has described a process for diene removal or, alternately, a two-

Table 15. Hydrogenation of pyrolysis gasoline (Shell Development)

Conditions	First stage	Second stage
Temperature, °C	80 – 130	230 – 380
Pressure, MPa	6	4.5 – 6.5

Bromine number g/100 g	60 – 100	25 – 80	25 – 80	1
Sulfur, ppm	100 – 400	100 – 400	100 – 400	0.5

stage process for diene removal followed by hydrogenation of sulfur and olefin compounds [64]. Diolefin hydrogenation is carried out in the first-stage reactor in a liquid flow with a special nickel-containing catalyst. Temperature control of the exothermic reaction is maintained by liquid product recycle. No desulfurization takes place in the first stage. If desired, olefins and sulfur may be removed in a second-stage hydrogenation in the presence of a nickel molybdate catalyst. Liquid product recycle may be used if necessary. Desulfurization and olefin saturation are nearly complete. Typical operating conditions when processing a C_5 – 200 °C pyrolysis gasoline charge are shown in Table 15.

A somewhat similar process has been described by the Institut Français du Pétrole. Reference [65] gives data for the hydrotreating of a C_5 – 205 °C pyrolysis gasoline. This is a one-stage process for the selective hydrogenation of diolefins or can be done as a two step process if complete hydrogenation of diolefins and olefins plus desulfurization is desired. Table 16 shows a partial listing of results.

In 1982, 65 units were in operation and others were under construction [65]. Several other processes of this type have been developed, including ones by British Petroleum [66] and Bayer.

Clay treating was formerly used for removal of diolefinic material and has been described in several publications. The process is outmoded, however, and is rarely used because of poor efficiency and disposal problems.

6.2. Close Fractionation

Precise fractionation may be used in some cases to separate nonaromatics from benzene or from other aromatics if the concentration of nonaromatics is not too great. However, some of the nonaromatics, such as cyclohexane, form azeotropes with benzene and thus cannot be completely separated by close fractionation at atmospheric pressure. In some cases distillation under elevated pressure will change the respective vapor – liquid equilibria so that separation may be improved.

6.2.1. Azeotropic Distillation

Naphthenes and paraffins are separated from aromatics by azeotropic distillation. Olefins in the charge mixture are generally detrimental to efficient separation. Usually the light ends from the crude BTX material are removed, followed by distillation of the benzene fraction from the toluene-xylene mixture. Examples of azeotrope formers include acetone and methanol with added water. Acetone is particularly suitable for the benzene fraction.

The azeotropic mixtures of nonaromatics and promoting agent are distilled. The nonaromatics are recovered by breaking the azeotropic mixture with water. In the benzene application, benzene is removed as a bottom product, washed, and distilled. Methanol is effective as an azeotrope forming agent in the treatment of the toluene – xylene fractions. By the azeotropic method, benzene with *fp* 5.5 °C is recovered in 98 % yield. Pure toluene is separated in 95 %

Table 16. Hydrogenation of C_5 – 205 °C pyrolysis gasoline (Institut Français du Pétrole)

	Feed-stock	After first stage	After second stage
Specific gravity	0.815	0.813	0.860
Diene value	30	1	≈0
Bromine number g/100 g	75	56	0.1
Sulfur, ppm	400	400	0.5

yield. Generally the process is limited to materials containing < 12 % nonaromatics. Azeotropic distillation has found limited application but is not as effective as other methods, such as extractive distillation and liquid-liquid extraction, in the isolation of high-purity aromatic compounds.

6.2.2. Extractive Distillation

Extraction and extractive distillation are commonly used to separate aromatics from crude BTX feeds. Extractive distillation is distinguished from normal distillation in that it is carried out in the presence of a high-boiling solvent having great solubility for aromatics and little or no solubility for paraffins and naphthenes. The solvent enters the distillation column near the top and above the point at which the BTX feed is introduced. The nonaromatics are distilled from the top of the column and the aromatic-rich solvent is withdrawn as a bottoms product. The aromatics are then distilled or stripped from the solvent in a second column and the lean solvent is recycled. Separation of the different aromatic components is carried out in subsequent distillation steps. Solvent to BTX feed ratios are generally in the order of 2 : 1 to 6 : 1 and conditions vary according to the nature of the solvent, column efficiency, and properties of the feedstock.

Extraction and extractive distillation methods as well as liquid – liquid extraction methods depend upon the use of very selective polar substances. Most of these compounds or solvents are high-boiling but some, such as SO_2, are not.

6.2.3. Liquid – Liquid Extraction

Liquid – liquid extraction in itself or in conjunction with other separation processes is the most widely used method for the isolation of aromatic fractions. All these processes involve the extraction of aromatics from nonaromatic material by the use of a polar solvent having a high-selective affinity for the former compounds.

The solvent, which is generally a high-boiling polar liquid, enters the top of the extractor vessel. Various designs of extractors have been used, including packed columns, sieve tray types, and others. A rotating disk contactor (RDC) has been used in some processes. The crude BTX or other aromatic-containing material enters near the middle of the extractors and thus contacts the solvent countercurrently in the column, or intimate contact is effected by other means. The nonaromatic raffinate leaves at the top of the extractor, whereas the aromatic-rich solvent is withdrawn at the bottom and passes to a distillation column, where the aromatics are taken overhead. The denuded solvent is then recycled to the extractor. The overhead aromatic stream is distilled to separate benzene and other aromatic components. The fundamentals of liquid – liquid extraction, extractive distillation, and various methods of aromatic recovery by extraction are discussed in [67], [68].

6.3. Processes for Aromatic Separation

Numerous methods and processes have been proposed and developed for the separation of pure aromatics from BTX feedstocks [69], [70]. The following are discussed in this article:

Process	Solvent
Edeleanu	sulfur dioxide
Udex	diethylene glycol and others
Sulfolane	sulfolane
Arosolvan	1-methyl-2-pyrrolidone
IFP	dimethyl sulfoxide
Formex	*N*-formylmorpholine
Morphylane	*N*-formylmorpholine

Edeleanu Process. This process uses as solvent liquid sulfur dioxide [*7446-09-5*], SO_2, M_r 68.06. It was developed in 1908 primarily for the

removal of aromatics from kerosine lamp oil and is of historical interest only. Liquid sulfur dioxide is effective in extracting of aromatics but is now used only for special purposes. This process is not competitive for aromatic removal in stocks with a high-aromatic content.

Udex Process (UOP-Dow). One of the early liquid – liquid extraction processes for the recovery of BTX aromatics from catalytic reformate was the Udex process [71], [72]. The process is also effective for recovering aromatics from coal tar, light oil, and pyrolysis gasoline. The first commercial installation was in conjunction with the UOP platforming unit at Cosden Petroleum Corp. [73].

The Udex process (see Fig. 10) uses diethylene glycol [*111-46-6*], 2-hydroxyethyl ether, $(HOCH_2CH_2)_2O$, M_r 106.12. The glycol contains about 8 % water to increase aromatic selectivity. This combination is effective as a solvent for separating aromatics from paraffins in the same boiling range. For aromatics production, a reformate fraction of 65 – 150 °C is charged to the liquid – liquid extractor where a multistage, countercurrent extraction takes place. The solvent enters at the top of the extractor column and passes countercurrent to the hydrocarbon feed, which is charged at an intermediate point. The raffinate passes overhead from the extractor. The aromatic-rich solvent is withdrawn from the bottom and passes to the solvent stripper, where the BTX material passes overhead and the denuded solvent is recycled to the extractor. The BTX mixture is washed with water and treated with clay before being separated into the benzene, toluene, and xylene by precise fractionation. Compounds of nitration grade specifications are obtained with only a small amount of xylene from the xylene distillation being lost from the bottoms. Typical results in the processing of catalytic reformate are shown in Table 17.

Improvements have been made in the Udex process in terms of solvent and of operating conditions. Aromatics recovery was improved and capacity was increased by using a solvent mixture of triethylene glycol and diethylene glycol or tetraethylene glycol. Pilot-plant studies carried out at Union Carbide showed that, where a solvent to feed ratio > 10 was required for high-aromatics recovery with diethylene glycol as the solvent, the ratio could be reduced to around 6 with the ethylene glycol – propylene glycol mixture. With tetraethylene glycol as the solvent, the ratio could be reduced to as low as 4 [74]. Operation at Sun Oil's Corpus Christi, Texas, plant [75] was improved when tetraethylene glycol was substituted for propylene glycol – ethylene glycol. Solvent/feed ratio was decreased with a resulting increase in capacity. Although the original process was based on the use of diethylene glycol as the solvent, most plants now use other more effective solvents, such as a tetraethylene glycol – water mixture.

Sulfolane Process. Shell Development Co. and Royal Dutch Shell have developed an aromatic extraction process based on the use of sulfolane as a selective solvent [76–79].

Sulfolane [*126-33-0*], tetramethylene sulfone, $C_4H_8O_2S$, M_r 120.17, is made by reacting sulfur dioxide and butadiene to form sulfolene, which is then hydrogenated to give sulfolane (→ Sulfones and Sulfoxides):

Some of the advantages of the sulfolane process are high selectivities and high yields. Also sulfolane has suitable physical properties, such as high density, low-heat capacity, and a boiling point high enough to permit easy separation for recycling. One disadvantage is thermal instability at the boiling point. However, this shortcoming is met by adding small amounts of water, which depresses the boiling point.

The sulfolane process (see Fig. 11) is similar to other aromatic extraction processes but differs in some operational procedures. The BTX containing feed is charged to a rotating disk contactor or extractor. Aromatics are extracted with a countercurrent flow of the sulfolane solvent. The aromatic-rich solvent from the bottom of the extractor passes to an extractive stripper. The overhead from this stripper is returned to the extractor as a backwash stream, for recovery of any residual aromatics. The aromatic – solvent mixture is charged to a recovery column where the aromatic product passes overhead. The lean solvent from the bottom of the column is recycled to the extractor.

A comparison of sulfolane with diethylene glycol [*111-46-6*] in the treating of light cat-

∗ Diethylene glycol

Yields and amounts of nonaromatic impurities (in parentheses) are: benzene, 99.9 % (0.01 %); toluene, 99.5 % (0.02 %); xylenes, 98.0 % (0.10 %).

As of 1980, over 55 sulfolane units were in operation with capacities ranging from a few hundred to over 45000 barrels/d [78].

Arosolvan Process. The Arosolvan process [81–83], licensed by Lurgi, uses an aqueous 1-methyl-2-pyrrolidone solvent. The water content ranges from 10 to 20 %, but is generally 12 to 14 %. Aromatics are extracted at 30 – 35 °C and at about atmospheric pressure. A comparison of properties of 1-methyl-2-pyrrolidone [*872-50-4*] and other solvents is shown in Table 19. Advantages of the Arosolvan process include operation of the extraction tower at atmospheric pressure and at room temperature, and low consumption of solvent (< 0.09 mg/L) [82]. Feedstocks may contain considerable unsaturates, and depentanization of the feedstock is not required because of the low-temperature operation of the extractor. Other advantages are clay treating of recovered aromatics is not necessary and waste disposal is not a problem because wash water is recycled.

Figure 12 is a simplified flow sheet of the process. The BTX feedstock is fed to the middle of the extractor where the aromatics are removed by countercurrent extraction with the solvent. The raffinate, containing pentane, other nonaromatics, and a trace of solvent, passes overhead from the extractor. The aromatic-rich solvent is passed to the first stripper, where pentane and some benzene passes overhead and, after joining with the overhead from the depentanizer, serves as a recycle stream to the bottom of the extractor. In the second stripper, high-purity aromatics and water are taken overhead while aromatics-free solvent is withdrawn from the bottom for recycle. The raffinate from the bottom of the depentanizing tower is separated from the solvent by water washing, and is removed from the process for fuel blending or other uses. The aromatic fraction from the overhead of the second stripper is separated by precise distillation.

Table 20 shows data obtained in the operation of two early commercial plants using the Arosolvan process. The Japanese plant operation involved the recovery of benzene, toluene, and xylene fractions from a feedstock composed of hydrogenated coal-gas and oil-gas benzene. The German operation used a hydrogenated pyrolysis gasoline as the feedstock.

DMSO Process. In 1965 the Institut Français du Pétrole described a process for the extraction of aromatics using dimethyl sulfoxide (DMSO) [*67-68-5*], $(CH_3)_2SO$, M_r 78.13, admixed with small amounts of water as the solvent (→ Sulfones and Sulfoxides) [84–86].

The DMSO process is shown in Figure 13. In the first extractor the BTX or other aromatic mixture is contacted at ambient temperature and atmospheric pressure in countercurrent fashion with the dimethyl sulfoxide solvent (containing < 9 % water). To maximize aromatic purity a mixture of aromatics and paraffins is fed to the bottom of the first extractor, countercurrent to the solvent flow, so as to combine reflux and backwash effects. The aromatic – solvent mixture passes from the first contactor to the second extractor where the DMSO solvent is recovered by re-extraction of the aromatics with a paraffin solvent. Extraction and re-extraction are carried out at room temperature and atmospheric pressure in rotating disk contactors of 10 – 12 theoretical stages. The paraffin – aromatic mixture from the second stage is separated by distillation and the paraffin is recycled to the second contactor. The small amount of DMSO that remains in the paraffin phase may be recovered by water washing. The DMSO is separated from the wash water by vacuum distillation.

Some of the advantages of this process are: DMSO has high selectivity for aromatic extraction; this selectivity is increased by the addition

of small amounts of water; extraction and re-extraction are carried out at room temperature and atmospheric pressure; and DMSO is non-corrosive and is chemically stable under process conditions.

Yield data for benzene, toluene, and xylene in the treatment of a catalytic reformate and a pyrolysis gasoline, after hydrogenation of olefins and diolefins, are presented in Table 21.

Formex Process. The Formex aromatic extraction process (SNAM Progetti) uses *N*-formylmorpholine (FM) in admixture with water as the extraction solvent for aromatics [87], [88]. The process is designed for the extraction of benzene, toluene, and xylenes from BTX feedstocks, such as catalytic reformates or hydrogenated pyrolysis gasoline. The process can be used also for the recovery of C_9 and C_{10} aromatics or for the removal of small amounts of aromatics from paraffinic hydrocarbon mixtures.

N-Formylmorpholine [*4394-85-8*], 4-formylmorpholine, 4-morpholinecarboxaldehyde, $C_5H_9NO_2$, M_r 115.13, has the following structure (→ Amines, Aliphatic):

The Formex process applied to the recovery of BTX components is shown in Figure 14 [83]. The BTX feedstock is charged at the middle of the extractor column.

Figure 14. Formex process, BTX extraction
a) Extractor; b) Stripper; c) Extraction column; d) Raffinate washer

Solvent enters at the top. Extractor conditions (atmospheric pressure, ca. 40 °C) are controlled so that the raffinate, containing a minimum amount of aromatics, passes overhead. The aromatic-rich solvent from the extractor is fed to the extractive stripper, where a stream of residual saturated hydrocarbons is taken overhead and returned to the extractor as reflux. The bottoms from this extractive stripper pass to the extract recovery column. Here the aromatics are taken overhead and the lean solvent is recycled to the extractor.

Typical yields and quality of products for a BTX charge containing 5 – 40 % benzene,

Table 21. DMSO process for aromatic extraction (yield data for different feedstocks)

	Catalytic reformate		Hydrotreated pyrolysis gasoline	
	Feed components, wt%	Aromatic recovery, wt%	Feed components, wt%	Aromatic recovery, wt%

15 – 30 % toluene, and 15 – 30 % xylenes are [89]:

	Benzene	Toluene	Xylenes
Yield, %	100	99	95 – 97
Nonaromatics, ppm	–	<200	<200
fp, °C	5.5		

The basic process may be modified. For benzene-rich feedstocks the liquid – liquid extraction column may be omitted and the feed charged in the vapor phase to a column where the raffinate, containing a minor amount of benzene, passes overhead and the aromatic-rich solvent from the extractor bottom is handled in the conventional manner. Other modifications include removal of minor amounts of aromatics from primarily saturated hydrocarbon stocks.

Commercial operations include a 500 $\times 10^3$ t/a BTX extraction unit and a 24×10^3 t/a unit producing aromatic-free aliphatic solvents from a $C_6 - C_7$ feedstock.

Morphylane Process. Krupp-Koppers has described processes for separation and recovery of BTX components from aromatic feedstocks, such as catalytic reformate and hydrogenated pyrolysis gasoline [90–92]. The Morphylane process is essentially an extractive distillation. The solvents used are derivatives of morpholine, principally *N*-formylmorpholine.

Generally, extractive distillation processes are used for the recovery of one aromatic component. The addition of *N*-formylmorpholine to the BTX mixture makes nonaromatics that boil above benzene more volatile than benzene. Therefore, these nonaromatics can be extractively distilled from a binary mixture of aromatics (e.g., benzene and toluene).

The *N*-formyl-morpholine, without added components, such as water, is fed at ambient temperatures to the top of an extractive distillation column (Fig. 15). It contacts a countercurrent flow of the preheated BTX feedstock, which is charged at a middle point in the column. The nonaromatics are distilled and leave at the top of the column. The aromatic-rich solvent is withdrawn from the bottom and passes to the stripper, where the aromatics are discharged overhead. The cooled, lean solvent is recycled to the top of the extractive distillation column. The recovery of benzene from a hydrogenated fraction of pyrolysis gasoline is 97 %, purity is 99.95 wt%, and $fp \geqq 5.5$ °C.

Figure 15. Morphylane extractive distillation process
a) Extractive distillation; b) Stripper

A toluene – xylene fraction from a feed consisting of catalytic reformate and hydrogenated pyrolysis gasoline, with morphylane processing under high-yield conditions, gives toluene in 99 wt% yield, purity > 99.9 %; and xylenes in 99.3 wt% yield, purity of 98 % [93].

A modified process for the combined and simultaneous recovery of BTX components from aromatic feedstocks, such as catalytic reformate or hydrogenated pyrolysis gasoline, has been described by Krupp-Koppers [94]. This process, called Aromex or Morphylex, combines liquid – liquid extraction with extractive distillation. In the liquid – liquid extraction stage, high-boiling nonaromatics are sep arated. In the extractive distillation stage, lower boiling nonaromatics are separated by extractive distillation. The overhead, after water removal, is fed back to the liquid – liquid extractor. The bottoms from the extractive distillation are passed to a stripper where the aromatics are distilled overhead and the solvent is recycled to the two extraction columns.

Typical data for the processing of a BTX – containing feedstock are:

	Benzene	Toluene	Xylenes
Yield, wt%	>99.9	>99.5	>97.0
Purity after fractionation	99.99	99.98	99.90

In 1982 six commercial units of the Morphylane process and one Morphylex unit were operating.

7. Quality Specifications

The ASTM has specified standards and test methods for benzene and related aromatic compounds. Likewise, specifications have been developed and used in other countries. As examples, the American National Standards have been used. The DIN Standards are used in Germany, and those of the Institute of Petroleum in England. The Technical Committee of ISO has standardized many of the specifications and test methods. Many of the ASTM methods have an Institute of Petroleum designation also.

The ASTM specifications for different grades of benzene are shown in Table 22. Test methods developed by ASTM are used in determining the specific properties of benzene:

1) Sampling: method D-270 for petroleum and petroleum products
2) ASTM D-891: specific gravity
3) ASTM D-1209: color
4) ASTM D-850: distillation
5) ASTM D-852: freezing point
6) ASTM D-848: wash color
7) ASTM D-847: acidity
8) ASTM D-849: copper corrosion
9) ASTM D-853: sulfur compounds
10) ASTM D-1685: thiophene
11) ASTM D-2360: nonaromatics

Similar specifications and tests have been developed for related aromatic compounds as well as for reagent grades of other materials; e.g., ASTM methods D-362–75 and D-841–71 describe standard specifications for industrial and for nitration-grade toluene.

The concentration of nonaromatics permitted in different grades of benzene is limited and in most cases must not exceed 0.15 %. For the 5.5 °C freezing point grade the maximum allowable is 0.01 %. The amount of paraffinic and naphthenic materials in the finished benzene is reflected in the boiling range and freezing point of the benzene.

The tests outlined by the ASTM methods and similar tests in different countries characterize benzene purity and whether or not the desired specifications are met. Gas chromatography is an important and efficient method for determining the presence of impurities in benzene and also the amount of benzene in different potential charge stocks available for the production of benzene.

8. Storage and Transportation

Benzene is a flammable, volatile, and toxic material, and its storage and transportation is closely regulated. Labeling is particularly important for the shipment of benzene. United States agencies involved in these regulations include OSHA, EPA, DOT, NIOSH, and others. The regulations dealing with handling and shipping are updated and published each year in the CFR. Other countries have regulations and safety practices quite similar to those in the United States. Although specific regulations must be met for manufacture, laboratory testing, storage, handling, and transporting of benzene, the safety rules are similar to those for other flammable and toxic liquids or gases.

Benzene is stored and transported in steel drums or tanks. Adequate ventilation is neces-

sary. Workers must be protected from skin contact or inhalation of fumes. Periodic physical examinations are recommended for those who work in areas where there is probable exposure to benzene. The handling of gasoline has caused concern because of its toxic components, which include benzene. Either CO_2 or dry chemical extinguishers are recommended for combatting benzene fires.

9. Economic Aspects

The demand for benzene as a raw material for the manufacture of petrochemicals has increased dramatically since the 1950s. Before World War II, light oil from coal carbonization was the main source for the production of benzene and the other BTX compounds. The development of new processes in the petroleum industry, such as catalytic reforming, provided a new raw material source for benzene. The rapid growth in the demand and production of benzene during 1950 – 1970, using United States production figures as an example, is shown in Table 23. The same increase in benzene production over the period before 1970 occurred in many other countries, especially those of Western Europe. For example, 1965 benzene production in the Federal Republic of Germany was ca. 330×10^3 t, but this had increased to ca. 820×10^3 t by 1970. Since the early 1970s the rate of growth in the quantities of benzene produced has leveled off somewhat, with downtrends apparent during periods of industrial recession. Because of decreased use of tetraethyllead in gasolines over the past several years, the demand for BTX aromatics in gasoline has increased. This may affect the overall demand and hence price level for benzene. Generally about 50 % of the benzene produced by petroleum refiners is retained for use as a gasoline component.

Benzene production by country over the past several years is shown in Table 24. Benzene production in 1980 for the non-communist world was over 13×10^6 t, with the United States producing about 40 % of the total [101]. An estimated annual growth of 2.0 – 2.5 % is predicted over the next years. The amount of benzene available from light oils produced in coal carbonization has not increased for some years, especially in the United States, for several reasons. Depression of the steel industry and the adoption of more modern steel processing methods have resulted in decreased coke production and hence decreased amounts of light oil. In addition, much of the light oil formed is not segregated but is burned as fuel in the steel industry. Petroleum refiners, however, purchase and refine this material because of its high content of benzene and appreciable amounts of the other BTX components. Table 25 shows the decline in coal-derived benzene in the United States since the 1950s. In 1953, 77 % of the benzene produced was derived from coal, but in 1981 this had decreased to 7 %. A further decline is projected. As mentioned earlier the change from coal-derived benzene to that produced by petroleum refiners came at a later date in Europe because of the greater dependency on coal. Thus in the Federal Republic of Germany in 1970, 38 % of the benzene produced was coal derived, as compared to

about 10 % in the United States. About 50 % of the light oils produced in the United States is processed into BTX materials for use as petrochemical charge stocks or as a motor fuel component.

Table 26 gives benzene production and sales by coke-oven operators and by petroleum refiners. The petroleum refinery figures include benzene derived from light oils purchased from coke-oven operators and processed by the petroleum refiners. The differences between the production and sales figures are indicative of the benzene retained by the petroleum refiners for use as fuel components.

Except for short intervals, production of benzene approximates demand. After a rapid growth in production facilities, the United States and other countries have production capacity far greater than demand. For the years shown, the ratio of benzene production to existing capacity was approximately [101]:

United States	1980	0.62
	1981	0.56
Western Europe	1980	0.59
Japan	1980	0.71

Demand is expected to increase moderately during the 1980s and the ratio may improve. On the other hand, with projected increase in demand, production capabilities may increase, especially in industrial developing countries and in countries with excess hydrocarbon supplies. Illustrative of this projected increase in capacity are the benzene projects planned or under construction in late 1981 [102]. The survey showed that 32 projects were being considered or under construction. In North America there were five units and in Western Europe four units. Eastern Europe with eight units and the Asian area with seven units indicate a rather sizable expansion. Eight units were planned for other areas.

Because toluene and xylenes are related components of BTX feedstocks and because the alkylated benzenes may serve as feedstocks for benzene production, the amounts of toluene and

∗ All grades, average

xylenes produced are of direct significance. Table 27 contains production figures for toluene and xylenes.

The prices of the BTX chemicals in the United States are documented annually by the United States International Trade Commission (USITC) [103]. Prices have fluctuated but in general have increased over the years (see Table 28). The values given in this table are for all grades and include values assigned to the aromatics retained and used as components in fuel blends. Some small variations in price are evident depending on the source and quality of the aromatic. For benzene in 1981, the all-grades average price was $ 0.45/L. Benzene from coke-oven sources commanded $ 0.44/L and 1 °C and 2 °C benzene from petroleum refiners averaged $ 0.45/L. Spot prices for benzene, toluene, and xylenes are published regularly in technical and trade journals. In the August 17, 1983 issue of Chemical Week [104], the price of benzene was $ 0.41/L or less, with toluene and xylenes endeavoring to command $ 0.29/L and $ 0.30/L, respectively. A comparison of benzene prices in July, 1982 for United States, Japan, and the Federal Republic of Germany as published by SRI International [101] showed roughly equivalent prices, with the United States price range of $ 0.40 – 0.41/L; Japan, $ 0.40 – 0.42/L; and the Federal Republic of Germany $ 0.38 – 0.40/L.

10. Uses

With the exception of its use as a motor fuel component and with the restrictions on its use as a solvent, the three main applications for benzene are production of ethylbenzene, cumene, and cyclohexane. These three products account for 75 – 80 % of the benzene consumed as a chemical feedstock. Table 29 gives 1980 benzene consumption by product [101]. A distribution of products and end uses of benzene in the United States is shown in Table 30.

Most of the primary products of benzene may be classified as intermediates. For example, benzene is alkylated with ethylene to form ethylbenzene, which in turn is dehydrogenated to styrene (→ Ethylbenzene, → Styrene). Styrene is the monomer employed for the production of several important polymeric or copolymeric products. These include acrylic – butadiene – styrene resins, styrene – butadiene rubber, and others [105].

Cumene, another large-volume product made from benzene, is used as a charge stock for the production of phenol and acetone. Cumene is made by the vapor-phase alkylation of benzene with propene. Most of the phenol produced in the United States and non-communist countries is derived from the hydroperoxidation of cumene. Phenol is used mainly for the production of phenolic resins.

Cyclohexane is the third largest volume intermediate product derived from benzene. It is produced by the direct hydrogenation of benzene [106]. Cyclohexane is oxidized to form intermediates, such as adipic acid, and thus serves as the starting point for the production of nylons.

About 5 % of the benzene produced is nitrated to form nitrobenzene, which in turn is hydrogenated to form aniline.

The oxidation of benzene is an established process for the production of maleic anhydride but it is receiving stiff competition from other processes, notably those involving the oxidation of butane and butenes. Maleic anhydride serves as a precursor for polyester resins.

Other products of benzene include the halogenated benzenes and the linear alkylbenzenes. The latter are a source for the production of detergents.

11. Toxicology and Occupational Health

Benzene has long been recognized as a toxic compound with both acute and chronic effects. Poisoning occurs through inhalation, ingestion, and by rapid absorption through the skin. Manifestations of acute benzene poisoning include headaches, confusion, loss of muscular control, and irritation of the respiratory and gastrointestinal tract. Greater concentrations may result in unconsciousness and even in death. Exposure to long-term chronic poisoning or shorter term exposure at higher concentrations may have drastic aftereffects, such as anemia and probably leukemia. Brain damage and damage to the urinary tract, mucous membranes, and other body parts were found in postmortem studies of acute and fatal poisoning [107].

Table 29. Benzene consumption in various countries (1980), 1000 t [101]

	United States	Western Europe	Canada	Mexico	Japan
Production	5293	4059	604	79	2046
Capacity	8578	6880	–	–	2882

∗ Projected

Inhalation of benzene at different concentrations in air is the most common source of benzene poisoning because benzene is rapidly absorbed by the lungs. Ingestion by mouth causes irritation of the mouth, esophagus, and stomach. Absorption of benzene by the blood may follow, with resultant chronic or acute poisoning. Absorption of benzene through the skin is not a major source of benzene poisoning [108].

The potential toxicity of benzene has been the subject of numerous studies [109], [110]. Benzene is selectively absorbed by the lungs [111]. About 80 % of the benzene inhaled by breathing air containing 3000 – 5000 ppm of benzene is retained. The benzene is absorbed by the blood and can become fixed in bone marrow, fatty tissues, and the liver. It is slowly metabolized to phenols and related compounds before being eliminated. Removal of benzene from the body by metabolism is determined by the presence of phenols in the urine. The phenols may act as toxic intermediates. The relationship between metabolism and benzene toxicity has been the subject of many studies [112], [113]. If benzene metabolism is inhibited by the addition of toluene, the destruction of red cell production is reduced [114]. Some inhaled benzene is slowly removed by exhalation. People breathing air containing 100 ppm benzene exhaled benzene 24 h after they ceased inhaling the benzene-contaminated air [115].

Susceptibility to benzene poisoning varies with the individual. Women, especially pregnant women, reportedly are more susceptible than men, but this has not been substantiated in other studies [116]. Individual susceptibility probably results from the natural resistance of the person or from the state of health at the time of exposure. Cases have been cited where workers, generally unconscious as a result of exposure to benzene fumes in enclosed areas, have recovered, whereas members of the rescue teams have died [117].

The literature is replete with references concerning the potential toxicity of benzene or that of its metabolized products and the var-

ious effects on the body. NTIS Report PB-289189 [118] reviews research findings of the effects of benzene poisoning at environmental exposure levels. Potential effects considered include leukemia, especially acute myelogenous leukemia, and pancytopenia (including aplastic anemia and chromosomal effects) and may result from long-term exposure. Again indications suggest that benzene toxicity and damage occur because of a toxic metabolite of benzene.

A group of chemical workers from seven industrial plants who had been exposed for 30 years to benzene for extended periods of time, but not necessarily continuously, were studied [119]. The incidence of various forms of cancer and the mortality rate of these workers was higher than, but not significantly above, those of the national norm.

Although conflicting reports have been issued over the years, it is generally believed that inhalation of benzene in occupational environments is potentially a cause of leukemia. An early indication of this relation was contained in a 1928 report [120]. In 1939, several cases of leukemia were reported in patients who had been chronically exposed to benzene [121]. In 1973, chronic benzene poisoning was thought to be responsible for four cases of acute leukemia. These patients had worked in an atmosphere containing 150 – 200 ppm benzene. According to other studies the connection between benzene poisoning and leukemia and other malignant conditions is much less certain. A 1974 survey included 38000 petroleum workers from eight refineries in Europe [122]. The purpose of the study was to determine if the incidence of leukemia could be related to workers chronically exposed to benzene at low-concentration levels. The conclusion was that the incidence of leukemia in the chronically exposed workers was not significantly different from that of the general population as a whole. However, this work has been criticized because of the different variables and assumptions made in the study. The results of other investigations indicate that benzene is suspected as a potential cause of leukemia.

Benzene toxicity has been related also to pancytopenia or destruction of elements in the blood. A related effect of benzene exposure is aplastic anemia in which bone marrow is damaged or destroyed. One early investigation studied workers in the printing industry who had been exposed for a long period to benzene vapors [123]. More recently the long-term effect of exposure to benzene has been studied. Partial recovery of blood and bone marrow damage may result on cessation of exposure if the damage has not been too great.

An EPA report [118] discusses the health effects caused by benzene at relatively low levels of concentration in terms of leukemia and blood disorders. Studies were made on humans and on animals.

Some investigations suggest that chromosome rearrangement may be caused by chronic exposure to benzene [110], [124]. Chromosomal damage of both stable and unstable nature can occur after benzene exposure. The stable effect was found to remain for several years. Alkylated benzenes did not cause this effect. These chromosome aberrations might result in the development of leukemia.

Although benzene has been universally recognized as a very toxic chemical compound with chronic and acute poisoning effects, questions still remain regarding its carcinogenicity. For instance, much research continues to determine whether benzene exposure results in leukemia. Studies have been done on animals and on groups of workers exposed to benzene vapors under varying operational conditions. Two examples of studies relating to leukemia indicate that much additional work is needed to sort out the complexities associated with the problem and to determine the quantitative level of exposure [125], [126].

Exposure to benzene emissions may occur from many sources. A major source of evaporative benzene emissions is from motor gasoline, both in exhaust gases from automobiles and from handling of gasoline during transport to service stations and from the filling of automobile tanks. Gasolines generally contain from 3 – 5 vol% benzene. Depending on control of emissions, a concentration of up to 3.2 ppm of benzene in the air may exist in the vicinity of the operation [127].

Another source of benzene emissions is in the manufacture of benzene and gasolines. Efficient process control in refineries, however, maintains evaporative losses at a minimum. Historically, a major source of benzene emissions was in the use of benzene or benzene-containing solvents in the formulation of paints, thinners, and ad-

hesives. Because of the high-toxic characteristics of benzene its use in these applications has been practically eliminated. Regulations state that substitute solvents should be used wherever possible. At one time alkylated mononuclear aromatics, such as toluene and xylene, were considered to have toxic effects equal to that of benzene. However, benzene is unique in most of its toxic effects. Earlier reports on the toxic effects of toluene and xylene may have overlooked the fact that benzene was present in these compounds [128]. The lower relative volatility of these alkylated aromatics is another factor in their favor.

Coal carbonization, for the production of coal coke for steel mill use, produces large amounts of aromatic compounds with benzene present in high concentrations.

Treatment for acute benzene poisoning is similar to that used for many cases of poisoning from toxic volatile chemicals. These steps include removing the person from the source, artificial respiration, if necessary, and other standard first-aid procedures.

Good laboratory and plant practices are paramount in preventing benzene poisoning. These involve minimum concentrations of benzene, either in liquid or vapor form, in work areas. Nonpermeable gloves have been suggested and tested as a means of preventing skin contact. Viton rubber or poly(vinyl alcohol) materials were found to be the best of those tested. However, these gloves are expensive and gloves are not always a guarantee of protection [129], [130].

The TLVs for benzene adopted by the ACGIH for 1983 – 1984 are: TWA 10 ppm, 30 mg/m^3; and STEL 25 ppm, 75 mg/m^3. Benzene is listed as a class A 2 industrial substance suspected of carcinogenic potential for humans (10 ppm) [131].

The DFG does not give a MAK for benzene but lists it in Section III A 1 under working materials which have been unequivocably proved carcinogenic. It is a compound capable of inducing malignant tumors as shown by experience with humans [132].

With the spotlight on the toxicity of benzene, tighter restrictions will probably be imposed on the use, the handling, and the exposure limits of benzene. The new regulations may be in the 1-ppm range. Recently the EPA has issued standards mostly aimed at benzene, projected to reduce emissions of volatile organic compounds by 70 %. This would apply to petroleum refineries and chemical plants [133].

Indicative of the activity and studies related to the toxicity of benzene and other poisonous materials, the following may be cited. A report on different carcinogens and methods for defining their risk factors has been issued by the Interagency Regulatory Liaison Group (IRLG) listing 26 substances, including benzene, and relating these to occupations that show high cancer rates [134].

The International Register of Potentially Toxic Chemicals (IRPTC) represents an international agency that is studying and registering the various effects of toxic chemicals under different conditions for each material. These conditions include factors related to production sampling, carcinogenicity, treatment of poisoning, and others [135].

The IRPTC was initiated in 1971 and is planning to publish its findings. The initial list of chemicals and products number 300 and more are to be added each year. The register is hoped to bring an international uniformity of information and control.

1. General Aspects

1.1. Physical Properties

The benzenesulfonic acids, with the exception of the aminobenzenesulfonic acids, are strong acids, which are almost entirely dissociated in aqueous solution. Some of them, including benzenesulfonic acid, can be distilled in a high vacuum without decomposition. They have a tendency to form hydrates, which are very stable in some cases and can be isolated from aqueous hydrochloric acid and dried at temperatures up to 100 °C without the water being lost. However, azeotropic distillation with benzene or chlorobenzene (depending on the heat stability of the hydrate) gives the anhydrous sulfonic acid.

Aminobenzenesulfonic acids are weak acids; they form zwitterions, which are poorly soluble in water, but their alkali salts are water-soluble. Unlike the free acids, the metal salts of the benzenesulfonic acids, particularly the alkali salts, are stable at temperatures up to and exceeding 300 °C. Most of them can be precipitated by adding an excess of salt to their aqueous solution. The calcium salts are more freely soluble in water than calcium sulfate. This is exploited industrially in the "liming" of the sulfonation mixture (see Section 2.2). In contrast to these metal salts certain organic salts are poorly soluble in water; for example, the salts with arylamines and *S*-benzylisothiourea have definite melting points and are therefore suitable derivatives for the identification of benzenesulfonic acids. compounds, see Section 1.9 and Chap. 2 of this article.

1.2. Chemical Properties

Desulfonation. The sulfonation of aromatic compounds to form arylsulfonic acids is a reversible reaction. It proceeds through various activated complexes and intermediates; Figure 1 shows a schematic plot of the enthalpy along the reaction coordinate. The ease with which sulfonation and desulfonation occur (kinetic control) and the position of the equilibrium (thermodynamic control) are dependent on the relative height of these enthalpies [8]. They are largely affected by other substituents present in the benzene nucleus. This is reflected by the various temperatures at which acidic desulfonation occurs [13]:

benzenesulfonic acid	227 °C
2-methylbenzenesulfonic acid	188 °C
4-methylbenzenesulfonic acid	186 °C
3,4-dimethylbenzenesulfonic acid	176 °C
3-methylbenzenesulfonic acid	155 °C
2,4-dimethylbenzenesulfonic acid	137 °C
2,4,6-trimethylbenzenesulfonic acid	100 °C

Figure 1 also explains the general rule according to which acidic desulfonation of benzenesulfonic acids occurs the more easily the easier it is to introduce the sulfonic acid group (higher sulfonation rate). This is often exploited industrially in the separation and purification of aromatic compounds as described in the next paragraph.

Pure *p*-xylene can be obtained from a mixture of *o*- and *p*-xylene by sulfonation and subsequent removal of water-soluble *o*-xylenesulfonic acid [14]. The same principle can be used to separate *m*-xylene from *p*-xylene [15], [16] and from ethylbenzene [17], or 1-ethyl-3,5-dimethylbenzene from other ethylxylenes [18], or 4-chloro-1,3-xylene from its isomers [19]. In the manufacture of DDT excess chlorobenzene was recovered by sulfonation, removal of the sulfonic acid, and subsequent desulfonation at 190 °C [20]. *m*-Dichlorobenzene can be separated as a sulfonic acid derivative from a mixture of isomeric dichlorobenzenes and obtained by subsequent desulfonation [21], [22]. The sulfonic acid group also serves as a protective group and permits the selective introduction of further substituents, e.g., in the manufacture of *o*-chlorotoluene:

2,6-Dichlorophenol and 6-halogeno-2-methylphenol can be produced analogously. In a similar manner 2,6- and 2,5-dichlorotoluene and 2,3,6-trichlorotoluene are obtained from toluenesulfonic anhydride by chlorination and subsequent desulfonation [24]. Sulfonation – desulfonation is also important in the production of 1,4-benzenedisulfonic acid (Section 2.2).

Alkali Fusion. Alkaline cleavage of benzenesulfonic acids leads to phenols according to the following equation:

$$ArSO_3Na + 2\,NaOH \longrightarrow ArONa + Na_2SO_3 + H_2O$$

In former times this was the method of choice to produce phenol on an industrial scale; however, this process has mostly been replaced by the Hock process (→ Acetone, Chap. 4.1.).

Sulfone Formation. Benzenesulfonic acids react with aromatic compounds to form sulfones. This reaction is an undesired side reaction in industrial sulfonation (see Section 2.1); it is promoted by Friedel – Crafts reagents and inhibited by alkali metal ions [25].

Reaction with Halogenides. The reaction with phosphorus halogenides (PCl_5, PBr_5), chlorosulfuric acid, thionyl chloride, or phosgene leads to sulfonyl halogenides:

$$C_6H_5SO_2OH + PCl_5 \longrightarrow C_6H_5SO_2Cl + POCl_3 + HCl$$

If benzenesulfonic acid reacts with an excess of PCl_5, chlorobenzene is formed according to

$$C_6H_5SO_2Cl + PCl_5 \longrightarrow C_6H_5Cl + SOCl_2 + POCl_3$$

Sulfonyl fluorides are obtained by the reaction of sulfonyl chlorides with KF in the presence of phase-transfer catalysts in sulfolane.

Anhydride Formation. Sulfonic anhydrides are made by the reaction of P_2O_5, $SOCl_2$, or SO_3 with benzenesulfonic acids [26]. They are

Figure 1. Sulfonation and desulfonation of benzene ($E^+ = SO_3$ or HSO_3^+), ΔH_R = reaction enthalpy

also formed through side reactions in the preparation of benzenesulfonic acids or benzenesulfonyl chlorides; in this case, however, they are frequently not observed because they are rapidly hydrolyzed in aqueous acid.

Esterification. Benzenesulfonic esters are formed in the reaction of the sulfonic acids or sulfonyl chlorides with alcohols or ethers (see Section 1.9.4).

1.3. Production

1.3.1. Direct Sulfonation

The direct introduction of the sulfonic acid group is one of the most important reactions in industrial organic chemistry. Together with nitration and chlorination, it belongs to the important group of electrophilic aromatic substitution reactions. It gives high yields under relatively mild conditions and usually results in well-defined benzene derivatives.

Aqueous sulfuric acid, at various concentrations from about 76 % up to 100 %, is frequently used as the sulfonating agent. In industry 100 % sulfuric acid is often called *monohydrate*. *Oleum* is a solution of sulfur trioxide in sulfuric acid; for sulfonation it is generally used at SO_3 concentrations of 20 or 65 wt % because the solidification points at these two concentrations are minimal (0 and 2 °C, respectively). Other concentrations are less favorable with regard to storage and transportation because the solidification points are higher (for example, 45 % oleum solidifies already at 35 °C) [27].

Sulfonation with sulfuric acid is a reversible reaction (see also Figure 1):

$$ArH + H_2SO_4 \rightleftharpoons ArSO_3H + H_2O$$

It can be shifted optimally to the right if the water of the reaction is bound or removed by distillation. Higher temperatures usually shift the equilibrium towards the right [28]. However, both methods increase sulfone formation.

The water of the reaction can also be bound by adding thionyl chloride:

$$C_6H_6 + H_2SO_4 + SOCl_2 \longrightarrow C_6H_5SO_3H + SO_2 + 2\,HCl$$

For example, the sulfonation of benzene with sulfuric acid and thionyl chloride gives a mixture consisting of 96.3 % benzenesulfonic acid, 2.7 % sulfuric acid, and 1.6 % diphenyl sulfone [29]. Similar yields are obtained when sulfonating toluene or chlorobenzene in this way.

No reaction water is formed in sulfonations using chlorosulfuric acid or sulfur trioxide. However, increased sulfone formation occurs. As a sulfonating agent pure *sulfur trioxide* generally reacts too violently and leads to extensive side reactions including oxidation and sulfone formation. Hence it is used in complexed form, e.g., with pyridine, dioxane, trimethylamine, or dimethylformamide [30]. Many industrial processes use sulfur trioxide gas as the sulfonating agent, normally mixed with an inert gas such as air, nitrogen, or carbon dioxide [31–33]. Thus, the sulfonating agent is diluted or evenly distributed so that the heat of the reaction is quickly dissipated [34] (see also → Surfactants). In the

liquid phase, sulfur dioxide or dichloromethane is suitable as diluent. However, dichloromethane reacts with sulfur trioxide at temperatures above 0 °C, and highly poisonous decomposition products are formed, such as bis(chloromethyl) ether. 1,1-Dichloroethane also reacts with sulfur trioxide at 80 °C; the decomposition products include phosgene.

In stoichiometric amounts, *chlorosulfuric acid* serves as a sulfonating agent according to

$$ArH + ClSO_3H \longrightarrow ArSO_3H + HCl$$

When using an excess of chlorosulfuric acid, sulfonyl chlorides are formed, see Section 1.9.1. The chlorosulfonation of toluene, for example, with chlorosulfuric acid at low temperature yields predominantly *o*-toluenesulfonyl chloride. This is the first step in the industrially important synthesis of saccharin (→ Sweeteners).

Reaction Mechanism. The basic reaction mechanism of aromatic sulfonation is described in Figure 1. The nature of the electrophilic agent E^+, however, varies according to the sulfonating agent used and the solvent.

In monohydrate (100 %) or only slightly diluted (92 – 99 %) sulfuric acid, sulfur trioxide is the electrophilic agent [35], [36]. The rate-determining step in this reaction is the elimination of the proton.

In sulfonation with disulfuric acid and with chlorosulfuric acid the SO_3H^+ cation (sulfate cation) is assumed to be the sulfonating agent [37]:

The SO_3H^+ cation is also formed as an intermediate when sulfur trioxide is used as the sulfonating agent [38–40]

Orientation Rules. The sulfonation of benzene derivatives C_6H_5Y is facilitated over that of benzene if the substituent Y supplies electron density to the aromatic ring. Examples are:

Substituent Y	Electronic effect
Alkyl	+I
OR, NR_2	+M > − I
O^-	+M; +I

where I = inductive effect and M = mesomeric effect

Benzene derivatives are sulfonated with greater difficulty than benzene if the substituent Y withdraws electron density from the aromatic ring. Examples are:

Substituent Y	Electronic effect
COR, COOR, CN, NO_2, N_2^+, SO_3H	−M; −I
Cl, Br	−I > +M
NR_3^+	−I

where I = inductive effect and M = mesomeric effect

The electron-releasing substituents and the halogens direct the SO_3H group predominantly into the *o*- and *p*-positions (*first-order substituents*). On the other hand, the electron-withdrawing substituents (except for the halogens) generally direct the SO_3H group into the *m*-position (*second-order substituents*). The seemingly exceptional role of the halogens is explained by the electronic stabilization of the various reaction intermediates (π complexes, σ complex); this is discussed extensively in textbooks on organic chemistry.

This fundamental rule of aromatic substitution is valid particularly at low temperature. Raising the temperature may change the isomer distribution in the product mixture due to the transition from kinetic to thermodynamic control. For example, sulfonation of benzene with sulfuric acid at about 80 °C yields predominantly 1,3-benzenedisulfonic acid (see Section 2.2); however, by raising the temperature to 250 °C an isomer mixture consisting of 67 % 1,3-disulfonic acid and 33 % 1,4-disulfonic acid is formed. When sulfonating first-order-

substituted benzene derivatives, the ratio of the *ortho* and *para* isomer formed is also shifted in favor of the *para* isomer if the temperature is raised.

Technology of Sulfonation. Sulfonation is carried out in cast-steel or enameled steel vessels; in continuous processes, the vessels are arranged in cascades. In the batchwise mode the sulfonating agent is introduced into the vessel, the aromatic compound is subsequently added, and the reaction is controlled by means of temperature profiles or metering. In continuously run cascades the sulfonating agent is often introduced into two or three vessels simultaneously.

On completion of the reaction the batch is forced into water, which causes unconverted aromatic compounds to be expelled. The dilute sulfonation mass is then cooled, and the free acid separated by filtration. If the free acid is too soluble, sodium sulfate or sodium chloride is added, after which the acid is separated as the sodium salt (salting out). Often it is also possible to neutralize a concentrated solution with sodium hydroxide and then remove the precipitated sodium sulfate at 70 – 90 °C. The filtrate then contains the sodium salt of the arylsulfonic acid almost free from inorganic salt. It can be dried in drum or spray dryers.

If isolation is not possible in this way, the excess sulfuric acid can be neutralized by adding calcium carbonate. This leads to a large amount of gypsum, which is removed in the hot state ("liming" or "chalking"). The dissolved calcium arylsulfonate is then treated with soda and the precipitated calcium carbonate is removed by filtration. The filtrate contains the sodium arylsulfonate. Today, in large-scale manufacture the economical removal of byproduct gypsum is, especially in Europe, very difficult, and other isolation techniques such as temperature-controlled crystallization or reactive extraction have become more favorable.

In the reactive extraction process the unconverted sulfuric acid is recovered by converting the sulfonic acid into its ammonium salt with a long-chain aliphatic amine. This salt is separated from the sulfuric acid as a liquid phase and then converted with sodium hydroxide solution into sodium sulfonate solution and the amine; the latter can be separated as a liquid phase and is re-used. Sulfonates practically free from inorganic salts are obtained in this way [41], [42].

Special sulfonation and processing methods have been developed for compounds that withstand high temperatures and therefore allow the excess sulfuric acid to be distilled off in vacuo (see Hooker process for the production of benzenedisulfonic acid, see page 15). This gives sulfonic acids almost free from sulfuric acid, which, with skillful mixing, can be neutralized and subjected to alkali fusion in a single step [43].

Aromatic amines may be sulfonated by a special solid-state process, called baking: the ammonium hydrogensulfate that is first formed in the reaction between the amine and sulfuric acid is dewatered and simultaneously rearranged to aminobenzenesulfonic acid at 150 – 300 °C. The reaction product is solid, which requires the reaction to be carried out on trays in an oven.

The solids can also be suspended in an organic liquid such as diphenyl sulfone [44] or *o*-dichlorobenzene [45]; in this way the mass can be stirred during the entire reaction. This gives final products of higher quality because local overheating cannot occur (see also manufacture of *p*-sulfanilic acid, see page 23).

1.3.2. Oxidation of Sulfur Compounds

Such sulfur compounds as thiophenols and diaryl disulfides can be oxidized with chlorine solution, permanganate, or nitric acid to form sulfonic acids. The process is industrially important wherever it is difficult or impossible to introduce the sulfonic acid group directly and the starting compounds are easily produced. An example of the use of halogens as oxidizing agents is given in [46].

1.3.3. Diazo Reaction

Aryldiazonium halides are converted to aromatic sulfonic acids in glacial acetic acid containing SO_2 in the presence of copper(I) chloride [47].

This reaction, which was first observed by L. Landsberg, permits the production of, for example, 1,2-benzenedisulfonic acid from orthoanilic acid with a yield of 68 % [48].

$$HO_3S{-}Ar{-}N{\equiv}N^+\ Cl^- + \tfrac{1}{2}\,Cu_2Cl_2 \longrightarrow$$

$$HO_3S{-}Ar{-}N{\equiv}N^+\ [CuCl_2]^- \longrightarrow$$

$$HO_3S{-}Ar\bullet + N_2 + CuCl_2 \xrightarrow[-\,N_2]{+\,SO_2}$$

$$HO_3S{-}Ar{-}SO_2\bullet + CuCl_2 \xrightarrow{H_2O}$$

$$HO_3S{-}Ar{-}SO_2OH + [CuCl_2]^- + H^+$$

1.3.4. Sulfite Reaction

Aromatic halogen compounds can react with sulfite to form sulfonic acids if the halogen substituent is activated by nitro groups. For example, 1-chloro-2,4-dinitrobenzene reacts with sulfite to give 1,3-dinitro-4-benzenesulfonic acid. The reaction is catalyzed by copper ions. 2-Formylbenzenesulfonic acid and 2-sulfobenzoic acid are obtained similarly from the corresponding chlorine compounds.

The addition of hydrogensulfite to aromatic systems succeeds when their aromatic character is disturbed by the presence of certain substituents. The formation of 3-hydroxybenzenesulfonic acid from resorcinol [49] and the sulfitation of *m*-dinitrobenzene with simultaneous reduction of a nitro group [50] (Piria reaction) are examples:

Hydrogensulfite addition, followed by the formation of a benzenesulfonic acid, gives satisfactory yields in special cases only and has therefore acquired little industrial importance so far.

1.4. Uses

Benzenesulfonic acids are used chiefly as intermediates. They are employed in the manufacture of sulfonic acid amides, hydrazides, and esters; of sulfinic acids, sulfones, phenols, and thiophenols; and of other compounds. Sulfonic acids that are substituted with OH and/or NH_2 groups serve as intermediates in the manufacture of finishing agents, optical brighteners, pickling agents, dyes, tanning agents, water-soluble resins, insecticides, ion-exchange resins, wetting agents, pharmaceuticals, polymeric thickeners, plasticizers, etc. Benzenesulfonic acids are also used as such as acidic catalysts and standardizing agents in dye manufacture.

1.5. Analysis

Today benzenesulfonic acids and most of their derivatives are analyzed by HPLC with high accuracy and efficiency [52]. By this method it is possible, both in the laboratory and in industry, to analyze the exact composition of sulfonation mixtures, which frequently consist of many components, and to observe how the composition is affected by the reaction parameters. Gas chromatography (GC) is used less often, but can be as effective, for example, after derivatization of reactive functional groups. GC methods have been reported for the analysis of *o*-aminobenzenesulfonic acids via their sulfonyl chlorides [51]. Benzenemonosulfonic and benzenedisulfonic acid mixtures can also be separated and analyzed quantitatively by GC analysis of their sulfofluorides [53].

In particular cases, benzenesulfonic acids are determined quantitatively in the presence of sulfuric acid and sulfones by titrating the total acid with alkali potentiometrically and then determining the sulfuric acid content gravimetrically with barium chloride. The difference gives the content of sulfonic acid. In general, in the case of the analysis of isolated salts of sulfonic acids,

the content should usually be referred to the free acid.

Older laboratory methods are the following: Aminobenzenesulfonic acids can be rendered distinctly visible on a paper chromatogram by diazotization and subsequent azo dye formation. Hydroxybenzenesulfonic acids can be stained well on the paper by coupling with a diazonium salt. Most other sulfonic acids can be recognized clearly from their fluorescence-extinguishing effects on chromatography paper previously sprayed with Pinakryptol Yellow and thus rendered fluorescent in UV light [54].

1.6. Environmental Aspects

Organic Compounds in Wastewater. Benzenesulfonic acid is biologically degradable. However, the direct biological degradation of many substituted benzenesulfonic acids is difficult or impossible; these compounds are therefore not suitable for treatment in biological wastewater purification plants without oxidative pretreatment.

If the desired benzenesulfonic acid can be precipitated from sulfuric acid solution without salt being added, the spent acid can be upgraded in a sulfuric acid recovery plant. If the wastewater contains salts and nondegradable sulfonic acids, low-pressure wet oxidation is a possible method of treatment that subsequently allows effective degradation in wastewater treatment works.

Inorganic Compounds in Wastewater. In the operation of large plants the treatment of such inorganic constituents as acids and salts is becoming an increasingly important cost factor in addition to the treatment of the organic constituents.

The following methods are available to decrease the acid or salt content of the wastewater.

1) Azeotropic distillation of the reaction water with a solvent. This improves the utilization of the sulfuric acid.
2) Use of oleum, sulfur trioxide, or chlorosulfuric acid in place of sulfuric acid. The resulting increase in sulfone formation can be counteracted, though not eliminated, with the aid of additives.
3) Precipitation of the final product from the sulfuric acid solution without adding salt, e.g., by cooling (see isolation of *p*-toluenesulfonic acid, see page 17).
4) Distillative separation of the sulfuric acid (see manufacture of benzenedisulfonic acid, see page 15).
5) Formation of a separate liquid phase consisting of an ammonium sulfonate. After phase separation, the sulfuric acid phase is returned to the sulfonation reactor.
6) Precipitation of the excess sulfuric acid as sodium sulfate if sodium sulfate is less soluble than the sodium sulfonate.
7) Precipitation of the excess sulfuric acid as calcium sulfate. The gypsum thus obtained is either dumped or used, depending on its quality.
8) Removal of the excess sulfuric acid by treating it with additional aromatic compounds that are more reactive than that used for the desired reaction. The resulting mixture could be subjected to alkali fusion to form phenols, which can be separated by distillation.

Waste Gas. The main organic constituents of waste air from benzenesulfonic acid production plants are unconverted portions of such starting materials as benzene, toluene, or halogenated benzene derivatives. They are usually removed in a sulfuric acid scrubber with a downstream thermal waste-gas remover. The waste sulfuric acid obtained in the scrubber can be recycled as a sulfonating agent. Because benzene is carcinogenic (Group C 1, MAK commission) the benzene emissions of newly built plants for the production of benzenesulfonic acid must be in accordance with the accepted lowest technically feasible levels.

Sulfur trioxide in waste gas forms aerosols that can only be removed effectively with specially designed scrubbers loaded with concentrated sulfuric acid. In most sulfonations the oxidative effects of sulfuric acid or sulfur trioxide lead to the formation of sulfur dioxide, which can suitably be removed from the waste gas by alkali scrubbing.

In the production of benzenesulfonyl chlorides the main impurity of the waste gas is hydrogen chloride. It can be used to produce hydrochloric acid or chlorosulfuric acid, provided that organic matter has been removed from it by

sulfuric acid scrubbing. Phosgene in the waste gas is hydrolyzed with water on activated carbon to form carbon dioxide and hydrogen chloride.

1.7. Economic Aspects

Most benzenesulfonic acids, chlorides, and amides are used as intermediates in the manufacture of dyes, crop protection agents, and pharmaceuticals. Because of the large number of producers and uses, little is known about exact market volumes. Especially in Asia and India the number of producers has increased, making the business for European suppliers increasingly difficult.

Table 1 lists some estimated production data for some benzenesulfonic acids, chlorides, and amides.

Table 1. Estimated production data for some benzenesulfonic acids, chlorides, and amides

	Production, 10^3 t/a	Year
p-Toluenesulfonic acid		
W. Europe	65.5	1990
World	115	1990
4-Aminobenzenesulfonic acid		
W Europe	11.5	1994

m-Aminosulfonic acid		
W. Europe	2.3	1994
China	5.0	1994
India	9.4	1994
Japan	1.0	1994
World	17.7	1994
2-Amino-1,4-benzenedisulfonic acid		
World	2.0	1995
2-Amino-5-chloro-4-methylbenzene-sulfonic acid		
World	9.9	1990
2-Formylbenzenesulfonic acid		
World	4.0	1996
2-Methylbenzenesulfonyl chloride		
World	11.2	1995
4-Methylsulfonamide		
World	10 – 15	1994

Some use of selected benzenesulfonic acids, chlorides, and amides follow:

p-Toluenesulfonic acid	resins, *p*-cresol, C-Acid, acid catalyst
4-Aminobenzenesulfonic acid	dyes, optical brightener
m-Aminosulfonic acid	dyes
2-Amino-1,4-benzenedisulfonic acid	dyes, optical brightener
2-Amino-5-chloro-4-methylbenzene-sulfonic acid	Lake Red C
2-Formylbenzenesulfonic acid	triphenylmethane dyes, optical brightener
2-Methylbenzenesulfonyl chloride	saccharin
4-Methylsulfonamide	plasticizer

1.8. Toxicology and Ecotoxicology

In general, benzenesulfonic acids, chlorides, and amides are not very toxic. Nevertheless, benzenesulfonic acids and chlorides are strong skin irritants. Amino substitution does increase their pK_a values, but aminobenzenesulfonic acids and -chlorides are still moderately irritant. In addition, benzenesulfonyl chloride can act as a skin sensitizer [55]. Benzenesulfonyl hydrazide is suspected to be mutagenic in vitro [56]. Concerning ecotoxicology, except for benzenesulfonyl chloride, none of the compounds listed in Table 2 represent a potential major hazard for aquatic ecosystems.

1.9. General Characteristics of Benzenesulfonic Acid Derivatives

1.9.1. Benzenesulfonyl Chlorides

Properties. The chlorides of benzenesulfonic acids are crystalline substances with definite melting points. They decompose with formation of sulfur dioxide at temperatures between 100 and 200 °C, depending on their structure. They undergo hydrolysis, which in some cases is very slow. Hydrolysis is accelerated by hydrogen ions; this explains why the decomposition of moist pastes may not occur until a considerable time has expired after their production, and why it may then take place exothermally and very rapidly, with the result that dangerous local overheating occurs. The chlorides of the benzenesulfonic acids react with amines to form sulfonamides and with alcohols to form esters.

Production. The most convenient method for the production of benzenesulfonyl chlorides is the *chlorosulfonation reaction* of benzene or substituted benzene with chlorosulfuric acid. Sulfonation and formation of the sulfonyl chloride take place in one reaction sequence:

Table 2. Toxicological and ecotoxicological data for benzenesulfonic acids and their derivatives

Compound	LD_{50} (rat, oral), mg/kg	Aquatic toxicity			Degradation	
		species	LC_0, mg/L	LC_{50}, mg/L	Test method	%
Benzenesulfonic acid	1170				Zahn – Wellens [57]	90

$$Ar{-}H + Cl{-}SO_3H \longrightarrow ArSO_3H + HCl$$

$$ArSO_3H + Cl{-}SO_3H \rightleftharpoons ArSO_2Cl + H_2SO_4$$

Sulfone is formed in a side reaction of the chlorosulfonation (up to 7 % of sulfone is formed when benzene is used as raw material and up to 35 % when chlorobenzene is used). It is attributed to the reaction of the initially formed sulfonic acid with unconverted aromatic compound:

$$ArSO_3H + ArH \longrightarrow ArSO_2Ar + H_2O$$

$$H_2O + ClSO_3H \longrightarrow H_2SO_4 + HCl$$

In this reaction the chlorosulfuric acid serves as a condensation agent.

The amount of sulfone formation can be reduced by diluting with a solvent, by using a large excess of chlorosulfuric acid, or by adding sulfone-inhibiting substances, e.g., alkali metal and ammonium salts, acetic acid, phosphoric acid, dimethylformamide, or amidosulfuric acid [59].

For *industrial chlorosulfonation* the chlorosulfuric acid is introduced into a cast-steel or enameled steel vessel and 10 – 25 mol % of the aromatic compound is stirred in at 25 – 30 °C, whereupon sulfonation of the aromatic compound and HCl formation occur. The formation of sulfonyl chloride is initiated by heating the reactants to 50 – 80 °C. The reaction is exothermic. The temperature must be controlled accurately to ensure uniform release of the HCl gas. Restarting of the agitator after an interruption of the electricity supply is hazardous and may cause the contents of the vessel to foam over. The sulfonyl chloride is isolated by draining the reaction mass onto water and simultaneous cooling. Excess chlorosulfuric acid is decomposed, and the sulfonyl chloride either precipitates or separates as an organic liquid phase. The quality of the chlorosulfuric acid affects the yield.

In the case of aromatic compounds that easily take up two sulfochloride groups, e.g., anisole, monochlorosulfonation is carried out with only a little more than the calculated amount of chlorosulfuric acid at a low temperature (0 °C) and in the presence of a diluent such as dichloromethane. The reaction of benzenesulfonic acids with chlorosulfuric acid is an equilibrium reaction. Therefore, the yield can be in-

creased by using an excess of chlorosulfuric acid [60].

Other chlorinating agents, such as phosgene, thionyl chloride, sulfuryl chloride, or phosphorus pentachloride, can be used instead of chlorosulfuric acid. When thionyl chloride is used the sulfonyl chloride is obtained from the sulfonic acid in high yield and without formation of sulfuric acid:

$$ArSO_3H + SOCl_2 \longrightarrow ArSO_2Cl + SO_2 + HCl$$

A one-pot procedure is described in [61]. According to [62] the highest degree of conversion is obtained in the presence of at least 5 % of a sulfonating agent, e.g., sulfur trioxide, or an excess of chlorosulfuric acid. If phosgene is used as a chlorinating agent, the reaction can be accelerated by adding dimethylformamide [62] or the less problematic dibutylacetamide for dimethylcarbamoyl chloride as byproduct is avoided. The crude sulfonyl chlorides can be purified either by fractional distillation or by crystallization from an anhydrous solvent.

In a *diazo reaction,* an NH_2 group can be ultimately replaced by the SO_2Cl group; this reaction is suitable for the preparation of special sulfonyl chlorides whose SO_2Cl group must be in a specific position [63]. A hydrochloric acid solution of the diazonium salt, whose concentration must be as high as possible, is allowed to flow into a $CuCl_2$-containing 30 % solution of sulfur dioxide in glacial acetic acid [64]. A similar procedure using thionyl chloride was also described [65]. Diazonium chlorides with substituents having a strong negative inductive effect (NO_2, SO_3H) give the best results. Poor yields can be improved by adding magnesium chloride or a water-immiscible solvent having a low dielectric constant. Disulfides can be converted into sulfonyl chlorides with chlorine in aqueous suspension. The reaction is also applicable to thiophenols.

$$(C_6H_5)_2S_2 + 5\,Cl_2 + 4\,H_2O \longrightarrow 2\,C_6H_5SO_2Cl + 8\,HCl$$

The dechlorosulfonation of benzenesulfonyl chlorides offers the possibility to selectively introduce chlorine into aromatics. 1,2,4-Trichlorobenzene can be produced from 1,2-dichlorobenzene without formation of undesirable tetra- or higher chlorinated products via chlorosulfonation and subsequent dechlorosulfonation at 200 °C and passing chlorine gas through the reaction mixture [66].

Due to their poor storage properties, many benzenesulfonic acids are reduced to the corresponding benzenesulfinic acids at 60 °C and pH 6 – 9.

$$ArSO_2Cl + NaHSO_3 + 3\,NaOH \longrightarrow ArSO_2Na + NaCl + Na_2SO_4 + 2\,H_2O$$

Sulfinates are often converted with ethylene oxide into β-hydroxyethylsulfones.

Uses. Benzenesulfonyl chlorides are important as intermediates. They are used to produce sulfonic acids, sulfonyl fluorides, sulfonamides, sulfonohydrazides, sulfonic esters, sulfinic acids, sulfones, and thiophenols.

1.9.2. Benzenesulfonamides

Properties. Benzenesulfonamides are readily crystallizing, colorless compounds with defined melting points and poor solubility in water. They are therefore suitable for the characterization of sulfonic acids (via the sulfonyl chlorides) and of primary and secondary amines and for the separation of amine mixtures (*Hinsberg method*) [67], [68].

Benzenesulfonamides are weak acids and form salts with bases. They are thermally stable and very difficult to hydrolyze with alkali; however, they are more easily hydrolyzed with mineral acids. In concentrated sulfuric acid sodium nitrite splits them into sulfonic acids and nitrogen. The hydrogen atoms bound to the nitrogen can be substituted.

Dibenzenesulfonylamines are acids similar in strength to the mineral acids [69]; they react with amines to form salts with definite melting points [70].

Production. Sulfonamides are produced by treating the sulfochlorides with ammonia, primary, or secondary amines in water. Alternatively they are produced in the presence of a base such as sodium hydroxide solution, sodium hydrogencarbonate, calcium carbonate, sodium sulfite, a second equivalent of amine or pyridine, or sodium acetate in glacial acetic acid; in this case, the reaction proceeds in an inert solvent, e.g., toluene or acetone.

Dibenzenesulfonylamines are obtained analogously according to the following reaction [71]:

$$2\,ArSO_2Cl + NH_3 \longrightarrow ArSO_2NHSO_2Ar + 2\,HCl$$

Unsymmetrical disulfonylamines are produced from sulfonamides and sulfochlorides in the absence of water [72] or in sodium hydroxide solution [73], [70].

Uses. Benzenesulfonamides serve as intermediates in the production of polysulfonamides, which are used as tanning agents and plastics. *N*-Alkylamides of the benzenesulfonic and toluenesulfonic acids can be used as plasticizers. Aminobenzenesulfonamides and diarylsulfonylamines with amino groups serve as intermediates in the production of azo dyes.

Sulfonamides, especially those derived from *p*-sulfanilic acid, sulfonyl ureas and sulfonyl guanidines are important in medicine as antibiotics, antidiabetics, diuretics, and anthelmintics [74], [75].

1.9.3. Benzenesulfonohydrazides

Properties. Benzenesulfonohydrazides, unlike the benzenesulfonamides, are thermally unstable. They decompose, when heated in water in some cases, to form sulfides, thiosulfonates, and nitrogen; for this reason they are used as blowing agents in the production of foams.

Production. Benzenesulfonohydrazides are produced by treating benzenesulfonyl chlorides with hydrazine in dioxane, alcohol, or water and in the presence of a second equivalent of hydrazine or another base. They react with nitrous acid to form benzenesulfonyl azides according to the following equation:

$$ArSO_2NHNH_2 + HNO_2 \longrightarrow RSO_2N_3 + 2\,H_2O$$

1.9.4. Benzenesulfonic Esters

Esters of benzenesulfonic acid are liquids or low-melting crystalline substances. They have relatively high thermal stability and can be purified by vacuum distillation. In general, they can be hydrolyzed with alkali at elevated temperatures only. The esters of benzenesulfonic acid are produced by treating benzenesulfonic acid halides with alcohols in the presence of a base [76], [77] or by treating benzenesulfonic acids with ethers [78]. These compounds are used as alkylating agents and plasticizers.

2. Individual Benzenesulfonic Acids and Derivatives

2.1. Benzenesulfonic Acid

Benzenesulfonic acid [*98-11-3*], $C_6H_5SO_3H$, M_r 158.17, was first obtained, together with diphenyl sulfone, by E. Mitscherlich in 1834 by heating benzene with fuming sulfuric acid. The industrially important reaction of benzenesulfonic acid with alkali hydroxide to form phenol (alkali fusion) was developed by A. Wurtz and A. Kekulé in 1867 and by P. O. Degener in 1878. Until the early 1960s benzenesulfonic acid was used chiefly in the manufacture of phenol. Other phenol syntheses are preferred now (→ Phenol).

Properties. Benzenesulfonic acid crystallizes from aqueous solution as a hydrate with $1.5\,H_2O$ in the form of deliquescent needles; its melting point is 43 – 44 °C. The monohydrate melts at 45 – 46 °C. The anhydrous acid, which can be distilled without decomposition at 171 – 172 °C (0.13 mbar), melts at 65 – 66 °C. It is very easily soluble in water and alcohol, poorly soluble in benzene, and insoluble in diethyl ether and carbon disulfide. Its dielectric constant in aqueous solution is 0.2. For the density and refractive indices of aqueous solutions, see [79].

Sodium benzenesulfonate decomposes at about 450 °C. It is soluble in 1.75 parts of water at 30 °C and in 0.8 part of boiling water, and crystallizes from aqueous solutions with 1 mol of water of crystallization. The calcium and barium salts are also soluble in water.

Benzenesulfonic acid has the characteristic reactions of a strong aromatic sulfonic acid. Acid hydrolysis at 175 °C splits it into benzene and sulfuric acid. Additional sulfonation with fuming sulfuric acid gives 1,3-benzenedisulfonic acid, which reacts further to 1,3,5-benzenetrisulfonic acid, and also diphenyl sulfone disulfonic acid (see Section 2.2).

Benzenesulfonic acid reacts with benzene to form diphenyl sulfone according to a Friedel – Crafts-type reaction:

$$C_6H_5SO_3H + C_6H_6 \xrightarrow{SO_3} C_6H_5SO_2C_6H_5 + H_2SO_4$$

Benzenesulfonic acid reacts with alkali metal hydroxide at 320 – 350 °C to form sodium phenolate according to

$$C_6H_5SO_3Na + 2\,NaOH \longrightarrow C_6H_5ONa + Na_2SO_3 + H_2O$$

This reaction was used in the first industrial synthesis of phenol.

Production. Benzenesulfonic acid is formed from benzene and sulfuric acid in an exothermic reaction according to

$$C_6H_6 + H_2SO_4 \longrightarrow C_6H_5SO_3H + H_2O$$

Crooks and White investigated the effects of temperature and of the composition of the sulfonation mixture on the reaction rate and developed a formula for calculating this rate [80]. The reaction stops at a particular sulfuric acid concentration between 74 and 78 %, which depends on the temperature and the amount of water formed. A proportion of the sulfuric acid (45 % in the classical process) is not utilized, but serves as a solvent and diluent and ensures that byproducts, particularly diphenyl sulfone, are formed in low yield only. In industry the excess acid is removed by adding calcium carbonate.

Any method that serves to reduce the excess of sulfuric acid increases the sulfone formation to a greater or lesser extent. The following methods have been used industrially:

1) Use of oleum or sulfur trioxide instead of sulfuric acid
2) Extraction of the benzenesulfonic acid from the reaction mixture with benzene
3) Azeotropic removal of the reaction water with benzene

Classical Process. The sulfonation by the classical process [81] is now of historical interest only, because it is coupled with the synthesis of phenol (use of sulfite from phenol production to neutralize the benzenesulfonic acid). Details of the process can be found in [82].

Continuous Sulfonation with Oleum (Monsanto process) [83]. Benzene and oleum are pumped simultaneously into the first of six sulfonation vessels forming a cascade. The vessels, which have propeller stirrers, are connected to one another by overflow pipes so that the reaction mixture can flow from one vessel to the next.

The first two vessels are cooled, whereas the others are heated. If optimal temperature conditions are provided, the reaction is complete when the sulfonation mixture leaves the last vessel. The excess sulfuric acid is removed by neutralizing the reaction mixture with sodium sulfite or sodium hydroxide solution. Sodium sulfate precipitates and is separated in a number of centrifuges. The solution of sodium benzenesulfonate is concentrated in an evaporator, which causes more sodium sulfate to precipitate. After centrifuging, the benzenesulfonic acid can be converted directly to phenol or dried. According to Carswell oleum containing 35.6 % of sulfur trioxide is used and the temperatures of the first and last sulfonation vessels are held at 70 – 80 °C and 110 °C, respectively. About 1 % of the benzene is converted to diphenyl sulfone.

Continuous Extraction Process. Under vigorous stirring excess benzene and sulfur trioxide are introduced into a vessel through separate pipes leading into the bottom of the vessel [84]. A benzene layer saturated with benzenesulfonic acid collects in the upper part of the vessel and passes through an overflow pipe into a second agitator vessel. In this vessel the benzenesulfonic acid is removed from the benzene extract by continuous washing with water or sodium hydroxide solution. The benzene is separated from

the aqueous benzenesulfonic acid solution in a separator. After being dried it is returned to the reaction vessel. The sulfuric acid consumption is 1260 kg for 1000 kg of converted benzene. Diphenyl sulfone formation is below 2 % [85].

Azeotropic Removal of Reaction Water [86], [87]. Sulfuric acid with a concentration of, for example, 79 % is heated to 170 °C in a cast-iron or enamelled steel sulfonation vessel and finely divided benzene vapor is introduced through a perforated plate situated in the lower part of the vessel. A portion of the benzene vapor, of which an excess is used, is sulfonated, whereas the unconverted portion continuously removes the water from the reaction mixture as it is formed. The mixture of benzene and water vapor leaving the vessel is condensed; after phase separation the benzene is returned to the evaporator.

Continuous operation of this process gives a final product containing 80.2 % of benzenesulfonic acid and 14.3 % of sulfuric acid; in batch operation the final product contains 93.1 % of sulfonic acid and 4.8 % of sulfuric acid. When adding sodium benzenesulfonate to the sulfonation mixture the sulfone formation can be kept below 2 % [88].

Analysis. A sample is taken from the sulfonation reactor and is diluted with water. Unconverted benzene is determined by gas chromatography, benzenesulfonic acid and diphenyl sulfone by high performance liquid chromatography. The sulfate concentration is determined at pH 2 – 3 by photometric titration with lead nitrate solution and dithizone (1,5-diphenylthiocarbazone) indicator in aqueous acetone solution [89].

Quality. Benzenesulfonic acid generally is sold as the sodium salt. This is almost colorless and without substantial impurities except for a small percentage of sodium sulfate.

Uses. Benzenesulfonic acid is used as an acid catalyst. The sodium salt is used to standardize dyes.

Benzenesulfonyl Chloride [*98-09-9*], $C_6H_5SO_2Cl$, M_r 176.62, $bp_{1013\,mbar}$ 251.5 °C, $bp_{13.3\,mbar}$ 120 °C, *mp* 14.5 °C, d_{15}^{15} 1.3842. Benzenesulfonyl chloride is made by treating benzene with chlorosulfuric acid at 30 – 35 °C [90]:

$$C_6H_6 + 2\,ClSO_3H \longrightarrow C_6H_5SO_2Cl + HCl + H_2SO_4$$

The sulfuric acid formed simultaneously inhibits the reaction. Therefore the yield of sulfonyl chloride is about 75 %, based on benzene. Benzenesulfonic acid and diphenyl sulfone are formed as byproducts in yields of approximately 18 % and 5 – 7 %, respectively.

The yield can be raised by partly replacing the chlorosulfuric acid with thionyl chloride. If this is done, the raw material and wastewater treatment costs are reduced, but the flue gas contains sulfur dioxide in addition to hydrogen chloride. Absorption of the gases in water recovers impure hydrochloric acid. The sulfur dioxide leaves the top of the hydrochloric acid recovery plant and can be used further in a sulfuric acid plant.

At the end of the reaction the products are cooled and simultaneously forced into a vessel containing water. The benzenesulfonyl chloride separates from the aqueous phase as a liquid organic phase. It is then washed twice with water and distilled; before that, the residual water is removed in vacuo. The main bottom product of the distillation column is diphenyl sulfone. The reaction can be carried out in vessels of cast iron or enameled steel.

Uses. Benzenesulfonyl chloride is produced on an industrial scale in Europe, the United States, and Japan. It is used as an intermediate for dyes and in the manufacture of benzenesulfinic acid, sulfonamides, and sulfonic esters. Benzenesulfonohydrazide serves as a blowing agent in the production of foams (trade name: Porofor BSH, Bayer).

Methyl Benzenesulfonate [*80-18-2*], $C_7H_8O_3S$, M_r 172.20, $bp_{20\,mbar}$ 150 °C, d_4^{17} 1.2730, is produced by treating benzenesulfonyl chloride with methanol in the presence of sodium carbonate [91] and is used as an alkylation agent. Yield: 87 %.

Ethyl Benzenesulfonate [*515-46-8*], $C_8H_{10}O_3S$, M_r 186.23, $bp_{20\,mbar}$ 156 °C, d_4^{17} 1.2192. Its manufacture and use are analogous to those of the methyl ester.

2-Chloroethyl Benzenesulfonate [*27887-43-0*], $C_8H_9ClO_3S$, M_r 220.67, $bp_{12\,mbar}$ 184 °C, d_4^{15} 1.353, is produced by treating 2-chloroethanol and benzenesulfonyl chloride at 12 – 15 °C (at most 25 °C) and adding sodium carbonate.

The reaction product is diluted with water and rendered alkaline by adding sodium carbonate. The organic lower layer is removed and distilled in vacuo [92]. Yield: 87.8 %, calculated on benzenesulfonyl chloride.

***p*-Chlorophenyl Benzenesulfonate** and **2,4-Dichlorophenyl Benzenesulfonate** are important as acaricides.

Benzenesulfonamide [*98-10-2*], $C_6H_5SO_2NH_2$, M_r 157.19, needles from water, flakes from alcohol, *mp* 156 °C. Obtainable from benzenesulfonyl chloride and ammonia. Used to manufacture chloramine B and dichloramine B (→ Chloroamines).

***N*-(Methyl)benzenesulfonamide** [*5183-78-8*], $C_7H_9NO_2S$, M_r 171.22, $bp_{22.5\,mbar}$ 202 °C, *mp* 30 °C, freely soluble in dilute alkaline solutions. Produced in the same way as the amide. Used as a plasticizer.

***N*-(Ethyl)benzenesulfonamide** [*5339-67-3*], $C_8H_{11}NO_2S$, M_r 185.25, *mp* 57 – 58 °C. Obtained as crystals from alcohol. Soluble in excess alkaline solution. Produced from benzenesulfonyl chloride with ethylamine and sodium carbonate. Yield: 98.7 % [93].

***N*-(Butyl)benzenesulfonamide** [*3622-84-2*], $C_{10}H_{15}NO_2S$, M_r 213.23, oil. Used as a plasticizer.

Benzenesulfonohydrazide [*80-17-1*], $C_6H_8N_2O_2S$, M_r 172.21, *mp* 101 – 103 °C, white powder, ϱ 1.48 g/cm^3, is used as a blowing agent in foam manufacture (Porofor BSH, Bayer).

4-[*N*-(Phenylsulfonyl)amino]acetanilide [*565-20-8*], $C_{14}H_{14}N_2O_3S$, M_r 290.34, *mp* 157 °C, crystallized from alcohol. Manufactured by treating 4-(amino)acetanilide with benzenesulfonyl chloride in water at 65 °C to which lime is added [94]. The compound is used to manufacture *N*-(4-aminophenyl)benzenesulfonamide.

1

***N*-(4-Aminophenyl)benzenesulfonamide** [*5466-91-1*], $C_{12}H_{12}N_2O_2S$, M_r 248.3, *mp* 171 – 172 °C. Made from the 4′-acetylaminoanilide by splitting off the acetyl group in an alkaline medium. Used as an intermediate for dyes.

***N*-(Phenylsulfonyl)benzenesulfonamide** [*2618-96-4*], $C_{12}H_{11}NO_4S_2$, M_r 297.35, *mp* 157 – 158 °C, poorly soluble in water and alcohol, insoluble in ether, slightly soluble in acetone. Sodium salt: *mp* 314 – 316 °C; anilinium salt: *mp* 176 °C. Manufactured by treating benzenesulfonamide in 5 % sodium hydroxide solution with benzenesulfonyl chloride at 50 – 55 °C (1 – 2 h). During the reaction the pH value must be kept at 7.2 by adding 5 % sodium hydroxide solution. At the end of the reaction the disulfonylamine is precipitated from the clear solution by adding hydrochloric acid. Yield: 70 – 98 % [95]. Additive for electroplating baths [96].

2.2. 1,3-Benzenedisulfonic Acid

1,3-Benzenedisulfonic acid [*98-48-6*] (**1**), $C_6H_6O_6S_2$, M_r 238.24, is a hygroscopic substance with a solidification point of 137 °C.

1

It is formed as the main product in the sulfonation of benzene or benzenesulfonic acid with excess oleum at temperatures of 80 – 250 °C. In proportion to the oleum concentration and reaction temperature

1 – 29 % of diphenyl sulfone disulfonic acid is formed as an undesired byproduct [97]. 1,4-Benzenedisulfonic acid is formed also, especially at high temperature, through rearrangement; mercury accelerates this process. At temperatures of 240 – 250 °C an equilibrium exists at a ratio of the *p*-acid to the *m*-acid of 1 : 2.

The disodium salt of 1,3-benzenedisulfonic acid is soluble in water at 27.5 °C to the extent of 41 %. With potassium or sodium hydroxide in aqueous solution under pressure it forms 3-hydroxybenzenesulfonic acid at 180 – 200 °C. At higher temperature resorcinol is formed.

Industrial Production [98]. Benzene is introduced into a cast-steel agitator vessel containing 100 % sulfuric acid. The contents of the reactor are heated to 100 °C and kept at this temperature for one hour. The products of the reaction (monosulfonation) are transferred to an agitator vessel containing 65 % oleum.

The temperature rises from 30 to 80 °C and is maintained at this level for another 1 – 2 h. The sulfonation mass is freed from sulfate ions in the normal way by adding calcium hydroxide or calcium carbonate and then removing the gypsum. It is then converted with sodium carbonate into the disodium salt, which is dried on a drum dryer. The yield is 93 % and the product has a purity of 96 %.

In a process patented by Farbwerke Hoechst [25] benzenesulfonic acid is mixed simultaneously with benzene and sulfur trioxide at temperatures above 120 – 140 °C. Sulfone formation is prevented by adding 3 – 15 % of the disodium salt of benzenedisulfonic acid. The excess of sulfur trioxide is about 0.2 mol per mole of benzene. The process can be operated continuously or discontinuously. After being neutralized with sodium hydroxide solution the final product can be melted to resorcinol directly. There is no necessity to remove sulfate ions. Excess sulfonating agent can be removed by subsequent reaction with benzene, toluene, or xylene. A mixture of resorcinol and phenol, cresol, or xylenol, is then formed by alkali fusion; the components of this mixture can be separated by distillation [99–101].

If benzene is sulfonated with 30 % oleum at 120 °C in the presence of sodium sulfate and the excess sulfuric acid is then converted into benzenemonosulfonic acid by introducing benzene vapor, a mixture of monosulfonic and disulfonic acid is obtained which can be used directly to produce phenol and resorcinol in the ratio 8 : 1 [99].

Particularly pure 1,3-benzenedisulfonic acid is obtained according to the process of Hooker Chemical Corp. [102]. Benzene is sulfonated with 96 % sulfuric acid at a molar ratio of the reactants of 1 : 3.4. The temperature is initially 65 °C, but is then raised to 80 °C. The water of the reaction is then removed by evaporation at 33 mbar and 200 °C. Finally, during disulfonation at 1.3 mbar and 210 – 235 °C, sulfuric acid and reaction water are distilled. The reaction product has a purity of 98.7 % and a solidification point of 136 °C. The process also can be operated continuously.

In a patent Koppers Co. [103] proposes that the disulfonation and simultaneous removal of water and excess sulfuric acid be carried out in a thin-film evaporator at a film thickness of 0.5 – 3 mm and a residence time of one minute. A vacuum of 13 mbar is claimed to be sufficient.

Uses. 1,3-Benzenedisulfonic acid is used to produce resorcinol and 3-hydroxybenzenesulfonic acid.

1,3-Benzenedisulfonyl Chloride [*585-47-7*], $C_6H_4Cl_2O_4S_2$, M_r 275.13, prisms from ether, *mp* 63 °C, $bp_{1.3\,mbar}$ 145 °C, $bp_{27\,mbar}$ 210.7 °C. Manufactured from *m*-benzenedisulfonic acid and phosphorus pentachloride or from benzenesulfochloride and chlorosulfuric acid. The compound is used to produce 1,3-benzenedisulfonohydrazide.

1,3-Benzenedisulfonamide [*3701-01-7*], $C_6H_8N_2O_4S$, M_r 236.27, obtained as needles from water, *mp* 229 °C. Manufactured from *m*-benzenedisulfochloride and aqueous ammonia.

1,3-Benzenedisulfonohydrazide [*4547-70-0*], $C_6H_{10}N_4O_4S_2$, M_r 266.31, white powder, *mp* 163 °C (decomp.), ϱ 1.24 g/cm^3, is suitable as a blowing agent for foams (Porofor B 13 CP 50, Bayer).

2.3. Alkylbenzenesulfonic Acids

This group of compounds comprises methylbenzenesulfonic acids (toluenesulfonic acids),

[*25231-46-3*], $C_7H_8O_3S$, M_r 172.20, methylbenzenedisulfonic acids (toluenedisulfonic acids) $C_7H_8O_6S_2$, M_r 252.26, dimethylbenzenesulfonic acids (xylenesulfonic acids) [*58723-02-7*], $C_8H_{10}O_3S$, M_r 186.23, and their derivatives.

Production. The sulfonation of toluene is accomplished more easily than that of benzene and is accompanied by less sulfone formation. Low temperatures favor *o*-substitution; *m*-substitution occurs only to the extent of about 2 – 3 %. At temperatures around 100 °C the ratio of *o*- to *p*-substitution is about 3 : 7. The sulfuric acid concentration has a strong influence on the isomer ratio [104]. Surprisingly, almost 100 % *p*-substitution is obtained at −10 °C if sulfur dioxide is used as the solvent [105].

At a sulfonation temperature of 100 °C and a sulfuric acid concentration of 97.4 %, 31 % *m*-substitution is achieved [106]. Through rearrangement at 140 – 200 °C the concentration of *m*-toluenesulfonic acid rises to about 46 % [107], [108]. If this is followed by hydrolysis with steam at 170 – 200 °C, the concentration of *m*-isomer rises to more than 90 % [109].

Isolation from the Mixture. *p*-Toluenesulfonic acid can be crystallized from 66 – 71 % sulfuric acid, or from concentrated hydrochloric acid at temperatures below 0 °C [110]. Then, according to the reaction conditions of the preceding sulfonation, the *o*- or *m*-toluenesulfonic acid can be obtained from the mother liquor. If the compounds are required to be very pure, the route via the toluidines (diazotization and reaction with sulfur dioxide) is preferred [47].

2,6-Toluenedisulfonic acid can be obtained by adding 65 % oleum to the sulfonation reaction mixture while the temperature is below 100 °C and then raising the temperature to 125 °C. In 90 % sulfuric acid at 190 °C, 64 % of the 2,4-toluenedisulfonic acid rearranges to 3,5-toluenedisulfonic acid. The 3,5-isomer is isolated from hydrochloric acid solution at −15 °C [111].

Uses. Toluenesulfonic acids are used as isomer mixtures, or as mixtures with xylenesulfonic acids; they serve as solubilizers, as acidic catalysts, and as additives for detergents [112]. They are used as intermediates in the production of cresols and sulfobenzoic acids.

2-Methylbenzenesulfonic Acid [*88-20-0*] (**2**), *o*-toluenesulfonic acid, $C_7H_8O_3S$, M_r 172.20, flaky crystals (dihydrate), *mp* 62.1 °C.

(**2**)

Produced together with 4-methylbenzenesulfonic acid by sulfonation of toluene with 96 % sulfuric acid at 40 °C, or preferably with 1 mol of chlorosulfuric acid at 0 to −10 °C. Used to produce *o*-sulfobenzoic acid.

2-Methylbenzenesulfonyl Chloride [*133-59-5*], $C_7H_7ClO_2S$, M_r 190.65, $bp_{13\,mbar}$ 126 °C, *mp* 15.5 °C. Manufactured by treating toluene with chlorosulfuric acid at temperatures not exceeding 3 °C, forcing the reaction mixture into ice, siphoning off the water, and centrifuging 4-methylbenzenesulfonyl chloride. Used in the production of toluenesulfonamide.

2-Methylbenzenesulfonamide [*88-19-7*], $C_7H_9NO_2S$, M_r 171.22, *mp* 156.5 °C, is obtained by treating 2-methylbenzenesulfonyl chloride with aqueous ammonia (*d* 0.910). Purified by fractional precipitation: hydrochloric acid is added to a solution which has been rendered alkaline with sodium hydroxide; the impurities are precipitated first. Used in the manufacture of saccharin (→ Sweeteners, Chap. 6.4.).

3-Methylbenzenesulfonic Acid [*617-97-0*] (**3**), *m*-toluenesulfonic acid, $C_7H_8O_3S$, M_r 172.20. The pure acid can be obtained from *m*-toluidine. Isomer mixtures with *m*-isomer concentrations of more than 50 % are obtained from toluene sulfonation mixtures by bubbling in toluene vapor at 180 – 205 °C [113], see also [109]. Used to manufacture *m*-cresol (→ Cresols and Xylenols).

(**3**)

3-Methylbenzenesulfonyl Chloride [*1899-93-0*], $C_7H_7ClO_2S$, M_r 190.65, $bp_{29\,mbar}$ 146 °C, *mp* 11.7 °C. Obtained from *m*-toluidine according to [33]. Yield: 71.2 %.

3-Methylbenzenesulfonamide [*1899-94-1*], $C_7H_9NO_2S$, M_r 171.22, *mp* 103 °C.

4-Methylbenzenesulfonic Acid [*104-15-4*] (**4**), *p*-toluenesulfonic acid, $C_7H_8O_3S$, M_r 172.20, *mp* 38 °C, monohydrate *mp* 106 °C, trihydrate *mp* 93 °C, $bp_{26.3\,mbar}$ 140 °C.

(**4**)

Production. According to the process of Allied Chemical and Dye Corp. [114], boiling toluene is sulfonated with 90 – 95 % sulfuric acid. Evaporating toluene is condensed, separated from water, dried, and recycled. A mixture with a *p*-isomer content of 75 – 85 %, an *o*-isomer content of 10 – 20 %, a *m*-isomer content of 2 – 5 %, and less than 1 % of sulfuric acid is present at the end of the reaction. There is very little sulfone formation. The process can also be performed continuously in a vertical reactor [116].

The reaction of toluene in a continuous process with sulfur trioxide as sulfonating agent allows toluenesulfonic acid to be generated with high *para* selectivity and with the advantage of few byproducts and low waste-gas emissions [115].

For some purposes, for example, for use as an acidic catalyst or in cresol manufacture, the crude toluenesulfonic acid obtained according to the above processes does not have to be purified. Purification is possible by crystallization from 66 % sulfuric acid or via the barium salt.

Uses. The applications of 4-methylbenzenesulfonic acid include the manufacture of 4-formylbenzenesulfonic acid, *p*-sulfobenzoic acid, 2-chlorotoluene-4-sulfonic acid, and 4-(chloromethyl)phenylmethanesulfonic acid.

4-Methylbenzenesulfonyl Chloride [*98-59-9*], tosyl chloride, $C_7H_7ClO_2S$, M_r 190.65, $bp_{25\,mbar}$ 138 – 139 °C, *mp* 69 °C. Formed as a byproduct in the manufacture of 2-methylbenzenesulfonyl chloride, from which it can be separated by remelting several times under water.

This compound is used in the production of sulfonamides, arylides, nuclear-substituted toluenesulfonyl chlorides, 4-(chloromethyl)benzenesulfonyl chloride, and *p*-toluenesulfinic acid. The tosylation of hydroxyl groups, i.e., their esterification with *p*-toluenesulfonyl chloride, serves to protect these groups; this method is employed particularly often in the chemistry of natural substances [117].

4-Methylbenzenesulfonamide [*70-55-3*], $C_7H_9NO_2S$, M_r 171.22, *mp* 137 °C, dihydrate *mp* 105 °C, weak acid, soluble in aqueous alkali. Produced from the sulfonyl chloride with aqueous ammonia. Used in the production of chloroamines, e.g., chloramine T and dichloramine T (→ Chloroamines).

Methyl 4-Methylbenzenesulfonate [*80-48-8*], $C_8H_{10}O_3S$, M_r 186.23, $bp_{17\,mbar}$ 168 – 170 °C, *mp* 28 °C, is obtained from the chloride of the acid by reaction with methanol; important alkylating agent.

Ethyl 4-Methylbenzenesulfonate [*80-40-0*], $C_9H_{12}O_3S$, M_r 200.26, $bp_{0.4\,mbar}$ 137 – 139 °C, $bp_{12\,mbar}$ 165 – 166 °C, *mp* 34 °C, is obtained from the sulfonyl chloride and ethyl alcohol at −5 to 0 °C after addition of 45 – 50 % sodium hydroxide solution [118]. Used as an alkylating agent and as a plasticizer.

4-(Chloromethyl)benzenesulfonic Acid [*46062-27-5*], $C_7H_7ClO_3S$, M_r 206.65, hygroscopic crystals, is obtained at a yield of 90 % through the action of chlorine on sodium 4-methylbenzenesulfonate in the presence of dichlorobenzene [119]. Used in the manufacture of surfactants.

4-(Chloromethyl)benzenesulfonyl Chloride [*2389-73-3*], $C_7H_6Cl_2O_2S$, M_r 225.09, *mp* 64 – 65 °C, $bp_{20\,mbar}$ 183 – 195 °C, is obtained by treating 4-methylbenzenesulfonyl chloride with chlorine in the presence of PCl_5 at 120 – 140 °C.

Methyl 4-(Chloromethyl)benzenesulfonate [*89981-68-0*], $C_8H_9ClO_3S$, M_r 219.67, is used as a quaternizing agent. Reactions with tertiary amines, e.g., trimethylamine, give sulfobetaines with fungistatic properties [120].

4-(Acetylaminomethyl)benzenesulfonyl Chloride [*39169-92-1*] (**5**), $C_9H_{10}ClNO_3S$, M_r 247.70, *mp* 95–97 °C, is obtained from *N*-acetylbenzylamine and chlorosulfuric acid [121].

(**5**)

4-(Acetylaminomethyl)benzenesulfonamide [*2015-14-7*], $C_9H_{12}N_2O_3S$, M_r 228.27, *mp* 177 °C (from water or aqueous alcohol), is produced from the sulfonyl chloride with aqueous ammonia at 15 and 70 °C; yield 80 %. It is an important intermediate in the manufacture of 4-(aminomethyl)benzenesulfonamide.

4-Methyl-1,3-benzenedisulfonic Acid [*121-04-0*] (**6**), $C_7H_8O_6S_2$, M_r 252.26, is a viscous oil. Obtained by additional sulfonation of the *o*- and *p*-toluenesulfonic acid mixture with 66 % oleum at 125 °C. Used in the manufacture of 4-formyl-1,3-benzenedisulfonic acid, 4-carboxy-1,3-benzenedisulfonic acid, and 4-methylresorcinol.

(**6**)

4-Methyl-1,3-benzenedisulfonyl Chloride [*2767-77-3*], $C_7H_6Cl_2O_4S_2$, M_r 289.16, *mp* 56 °C, is produced from toluene and chlorosulfuric acid at 120 °C [122]. Addition of phosphorus pentoxide raises the yield [123].

4-Methyl-1,3-benzenedisulfonamide [*717-44-2*], $C_7H_{10}N_2O_4S_2$, M_r 250.30, *mp* 190–191 °C.

2,4-Dimethylbenzenesulfonic Acid [*88-61-9*] (**7**), *m*-xylenesulfonic acid, $C_8H_{10}O_3S$, M_r 186.23, dihydrate: *mp* 57 °C, prisms or flakes. Produced by sulfonating *m*-xylene with concentrated sulfuric acid; the acid is precipitated by dilution with water. Of the three isomeric xylenes, *m*-xylene is the one most easily sulfonated. The ease of sulfonation decreases in the order $m>p>o$, whereas the ease of hydrolysis increases in the order $o<m<p$. *m*-Xylenesulfonic acid is hydrolyzed at 180 °C. Used in the production of nitroxylenesulfonic acid, chloroxylenes, and chloroxylenesulfonic acids.

(**7**)

2,4-Dimethylbenzenesulfonyl Chloride [*609-60-9*], $C_8H_9ClO_2S$, M_r 204.68, *mp* 34 °C.

2,4-Dimethylbenzenesulfonamide [*7467-12-1*], $C_8H_{11}NO_2S$, M_r 185.25, *mp* 138 °C.

2,5-Dimethylbenzenesulfonic Acid [*609-54-1*] (**8**), $C_8H_{10}O_3S$, M_r 186.23, *mp* 48 °C, *bp* 149 °C (cathode vacuum), is soluble in chloroform. The dihydrate, *mp* 95 °C, is obtained by sulfonating *p*-xylene with 93 % sulfuric acid and removing the water by distillation [124]. Used in the production of 2,5-xylenol.

(**8**)

2,5-Dimethylbenzenesulfonyl Chloride [*19040-62-1*], $C_8H_9ClO_2S$, M_r 204.68, *mp* 25.5 °C, $bp_{29\,mbar}$ 152 – 153 °C.

2,5-Dimethylbenzenesulfonamide [*6292-58-6*], $C_8H_{11}NO_2S$, M_r 185.25, *mp* 148 °C.

4-Ethylbenzenesulfonic Acid [*98-69-1*], $C_8H_{10}O_3S$, M_r 186.21, is produced by sulfonating ethylbenzene with sulfuric acid. It is separated from the isomers via the aniline salt [125]. Used in the production of *p*-ethylphenol.

4-(2-Bromoethyl)benzenesulfonic Acid [*54322-31-5*] (**9**), $C_8H_9BrO_3S$, M_r 265.13; *S*-benzylisothiuronium salt, *mp* 149 – 150 °C. The acid is obtained by sulfonating 1 mol of (bromoethyl)benzene with 1.1 mol of SO_3 in methylene chloride [126], see also [127], [128]. The potassium salt is obtained by treating the sulfonyl chloride with potassium carbonate in water [129].

(**9**)

4-(2-Bromoethyl)benzenesulfonyl Chloride [*64062-91-5*], $C_8H_8BrClO_2S$, M_r 283.58, is produced from 2-(bromoethyl)benzene and chlorosulfuric acid at temperatures not exceeding 25 °C [130]. Used in the production of 4-vinylbenzenesulfonic acid.

4-(2-Bromoethyl)benzenesulfonamide [*5378-84-7*], $C_8H_{10}BrNO_2S$, M_r 264.15, *mp* 185.5 – 186 °C.

4-Vinylbenzenesulfonic Acid [*98-70-4*] (**10**), $C_8H_8O_3S$, M_r 184.21; *p*-toluidine salt, *mp* 182 – 183 °C, is obtained in the form of the potassium salt from 4-(2-bromoethyl)benzenesulfonic acid with methanolic KOH [131] or from 4-(2-bromoethyl)benzenesulfonyl chloride with alcoholic KOH [132]. The monomer can be stabilized by adding 0.5 – 5 % of sodium nitrite [133].

(**10**)

4-Vinylbenzenesulfonic acid has been proposed for copolymerization with acrylonitrile to improve the dyeing properties of the fibers [134] and as a starting product in the manufacture of polymeric styrenesulfonic acid [131], [132].

4-Vinylbenzenesulfonamide [*2633-64-9*], $C_8H_9NO_2S$, M_r 183.23, *mp* 138 – 139 °C [135].

4-*tert*-Butyl-2,6-dimethylbenzenesulfonic Acid [*28188-48-9*] (**11**), $C_{12}H_{18}O_3S$, M_r 242.31, is prepared from 1-*tert*-butyl-3,5-dimethylbenzene with 5 % oleum at 20 – 45 °C. Used in the manufacture of 4-*tert*-butyl-2,6-dimethylphenol and 2,6-xylenol [136].

(**11**)

2,3-Dihydro-1*H*-indene-5-sulfonic acid [*40117-41-7*] (**12**), $C_9H_{10}O_3S$, M_r 198.24, is obtained by precipitation as a sodium salt, after 2,3-dihydro-1*H*-indene and concentrated sulfuric acid have been reacted at 150 °C [137]. At low temperatures mainly 1*H*-indene-4-sulfonic acid is formed. 1*H*-Indene-5-sulfonic acid has been proposed as a starting material for the manufacture of sulfonylureas with hypoglycemic effects [138].

(**12**)

2,3-Dihydro-1*H*-indene-5-sulfonyl Chloride [*52205-85-3*], $C_9H_9ClO_2S$, M_r 216.69, *mp* 49 °C, $bp_{21\,mbar}$ 180 °C, is obtained by treating

the sodium salt of 1*H*-indene-5-sulfonic acid with PCl_5, or by the reaction of 2,3-dihydro-1*H*-indene and chlorosulfuric acid at 0 – 15 °C, pouring onto ice, and extracting with chloroform [139].

2,3-Dihydro-1*H*-indene-5-sulfonamide [*35203-93-1*], $C_9H_{11}NO_2S$, M_r 197.26, *mp* 135 °C.

2.4. Formylbenzenesulfonic Acids

2-Formylbenzenesulfonic Acid [*91-25-8*] (**13**), $C_7H_6O_4S$, M_r 186.18, is obtained as a thick syrup by treatment of its barium salt with sulfuric acid. Acquires a deep reddish-violet color if Schiff's reagent is added. In contrast to the poorly soluble barium salt, the sodium salt is freely soluble in water; it is also freely soluble in hot, but not in cold, ethyl alcohol.

(**13**)

Production. The starting material is *o*-chlorobenzaldehyde, which is heated with sodium hydrogensulfite solution in an autoclave to 190 – 200 °C, with the result that its chloro substituent is replaced by the sulfonic acid group. The batch is allowed to cool, sulfuric acid is added, and excess sulfur dioxide and unconverted chlorobenzaldehyde are driven off by boiling. The resulting solution is used directly in the manufacture of dyes. The acid can also be produced by oxidation of *o*-toluenesulfonic acid with oxygen in the presence of bromine and cobalt as catalysts [140].

Uses. 2-Formylbenzenesulfonic acid is an intermediate in the manufacture of optical brighteners [141], trade names including Uvitex NFW (for textiles) and Tinopal CBS (for detergents). Triphenylmethane dyes are produced by condensation of the acid with various *N,N*-dialkylanilines, *N,N*-dialkyl-*m*-aminophenols, and their sulfonic acids.

4-Formylbenzenesulfonic Acid [*5363-54-2*] (**14**), $C_7H_6O_4S$, M_r 186.18. The thiosemicarbazone decomposes at 230 °C. 4-Formylbenzenesulfonic acid is produced by oxidation of *p*-toluenesulfonic acid with manganese dioxide in 25 % oleum or by oxidation of *p*-toluenesulfonyl chloride in glacial acetic acid – acetic anhydride with chromium trioxide and concentrated sulfuric acid at 0 °C and hydrolysis of the sulfonyl chloride of the aldehydehydrate diacetate with dilute hydrochloric acid [142].

(**14**)

4-Formyl-1,3-benzenedisulfonic Acid [*88-39-1*] (**15**), $C_7H_6O_7S_2$, M_r 266.25, is freely soluble in water. The sodium salt crystallizes with 2 mol of H_2O and is freely soluble in water and poorly soluble in ethyl alcohol. It is made by reaction of 2,4-dichlorobenzaldehyde with sodium hydrogensulfite liquor or oxidation of 2,4-toluenedisulfonic acid with manganese dioxide in sulfuric acid. The acid is used in the production of triphenylmethane dyes and wetting agents.

(**15**)

2.5. Chlorobenzenesulfonic Acids

4-Chlorobenzenesulfonic Acid [*98-66-8*] (**16**), $C_6H_5ClO_3S$, M_r 192.62, *mp* 68 °C, deliquescent needles, is soluble in water and ethanol. Prepared by sulfonation of chlorobenzene with sulfuric acid; the water formed in the reaction is removed continuously. It can be hydrolyzed to chlorobenzene with steam at 190 °C [143] and is used in the manufacture of 4-chloro-3-nitrobenzenesulfonic acid.

(**16**)

4-Chlorobenzenesulfonyl Chloride [*98-60-2*], $C_6H_4Cl_2O_2S$, M_r 211.01, $bp_{16\,mbar}$ 140 °C, *mp* 55 °C, is manufactured by mixing 4-chlorobenzene and chlorosulfuric acid at 35 °C, heating for two hours at 80 °C, and discharging the contents of the reactor into ice water; yield 81 % of theory, together with a small amount of bis(4-chlorophenyl) sulfone [145], [146]. Used in the manufacture of chlorobenzenesulfinic acid and sulfimides; three-step reaction to the sulfone in a single reactor is possible without intermediate isolation [147].

4-Chlorobenzenesulfonamide [*98-64-6*], $C_6H_6ClNO_2S$, M_r 191.63, *mp* 146 °C, is freely soluble in ethyl alcohol, ether, and hot water.

4-Chloro-*N*-[(4-chlorophenyl)sulfonyl]-benzenesulfonamide [*2725-55-5*], $C_{12}H_9Cl_2NO_4S_2$, M_r 366.24, *mp* 298 °C (from water), is prepared by treating the corresponding sulfonyl chloride with 0.45 mol of ammonium chloride at 0 – 3 °C, with dropwise addition of sodium hydroxide solution at pH 8; yield 91 % [148]. Used as a reagent for identifying amines.

2,5-Dichlorobenzenesulfonic Acid [*88-42-6*] (**17**), $C_6H_4Cl_2O_3S$, M_r 227.06, crystals, freely soluble in water. Obtained by sulfonating 1,4-dichlorobenzene with oleum.

(**17**)

2,5-Dichlorobenzenesulfonyl Chloride [*5402-73-3*], $C_6H_3Cl_3O_2S$, M_r 245.51, *mp* 39 °C, needles (from ethyl alcohol), is made by treating 1,4-dichlorobenzene with chlorosulfuric acid at 150 °C and stirring into ice water; yield 85 % [149]. It has been described as a modifier for Nylon 6 [150].

3,4-Dichlorobenzenesulfonic Acid [*939-95-7*] (**18**), $C_6H_4Cl_2O_3S$, M_r 227.06, is poorly soluble in water; the calcium salt is freely soluble, barium and lead salts are slightly soluble. Manufactured by sulfonating *o*-dichlorobenzene with oleum [151].

(**18**)

3,4-Dichlorobenzenesulfonyl Chloride [*98-31-7*], $C_6H_3Cl_3O_2S$, M_r 245.51, *fp* 22.4 °C, is manufactured from *o*-dichlorobenzene and chlorosulfuric acid; used as an inexpensive acylating agent.

3,4-Dichlorobenzenesulfonamide [*23815-28-3*], $C_6H_5Cl_2NO_2S$, M_r 226.08, *mp* 140 °C.

2,4,5-Trichlorobenzenesulfonic Acid [*6378-25-2*] (**19**), $C_6H_3Cl_3O_3S$, M_r 261.51, is obtained in the form of the sodium salt by sulfonating 1,2,4-trichlorobenzene with 25 % oleum and pouring the clear sulfonation mixture into a solution of sodium chloride in water; yield 94 – 95 %.

(**19**)

2,4,5-Trichlorobenzenesulfonyl Chloride [*15945-07-0*], $C_6H_2Cl_4O_2S$, M_r 279.96, *mp* 65 – 67 °C (from petroleum ether), $bp_{0.6\,mbar}$ 138 °C, is obtained from trichlorobenzene by chlorosulfonation with chlorosulfuric acid at 90 °C and pouring the reaction mass into water [152–154].

Esters and amides of several chlorobenzenesulfonic acids (particularly 4-chlorobenzenesulfonic acid, 2,5-dichlorobenzenesulfonic acid,

and 2,4,5-trichlorobenzenesulfonic acid) have acquired some importance as crop protection products and agents for the control of fiber pests.

2.6. Aminobenzenesulfonic Acids

The rearrangement of the *N*-phenylsulfamic acid initially formed in the sulfonation of aniline is dependent on temperature. At elevated temperatures it gives 4-aminobenzenesulfonic acid almost quantitatively.

Even at low temperatures, the two other isomers are formed in only relatively small amounts. They are therefore manufactured industrially in other ways (see below).

For identification, aromatic aminosulfonic acids cannot be converted into amides via the sulfonyl chlorides; they must first be converted to the corresponding chlorobenzenesulfonic acids by Sandmeyer's reaction [155], and then derivatized. Today, identification is by HPLC.

2-Aminobenzenesulfonic Acid [*88-21-1*], $C_6H_7NO_3S$, M_r 173.19, is obtained as a byproduct in the manufacture of 3-aminobenzenesulfonic acid by nitration of benzenesulfonic acid at 100 °C, separation of the resulting nitrobenzenesulfonic acids via the magnesium salts, and reduction with iron turnings.

In the reaction between amidosulfuric (sulfamic) acid and excess aniline at temperatures up to 160 °C, 2-aminobenzenesulfonic acid and 4- aminobenzenesulfonic acid are obtained in a ratio of 3 : 2 [156]. The two isomers are separated by means of their different solubilities in aqueous KOH [157].

2-Aminobenzenesulfonic acid is obtained from 2-nitrothiophenol by boiling in a mixture of dioxane and water (ratio 20 : 1) for seven hours; the yield is 86.7 % of theory [158]. The acid can also be produced as follows: 2-chloronitrobenzene is reacted with sodium disulfide in aqueous alcoholic solution to form 2,2′-dinitrodiphenyldisulfide. After having been dissolved in a mixture of hydrochloric acid and nitric acid this is oxidized with chlorine to form 2-nitrobenzenesulfonyl chloride [159], which is then hydrolyzed with soda solution and finally reduced with iron turnings [160]. Alternatively 2,2′-dinitrodiphenyl disulfide can first be reduced to 2,2′-diaminodiphenyl disulfide and then oxidized with hydrogen peroxide in aqueous sulfuric acid to 2-aminobenzenesulfonic acid [161], [162].

2,2′-Diamino-diphenyldisulfide can also be arrived at by alkaline hydrolysis of benzothiazole or mercaptobenzothiazole, followed by oxidation with hydrogen peroxide. The additional oxidation leading to 2-aminobenzenesulfonic acid can be performed in alkaline solution. Thus the synthesis starting from benzothiazole can be carried out exclusively in alkaline solution in a single reactor [163]. Yield: 70 %, based on benzothiazole.

2-Aminobenzenesulfonamide [*3306-62-5*], $C_6H_8N_2O_2S$, M_r 172.21, *mp* 153 °C, crystals (from water), is freely soluble in water, glacial acetic acid, ethyl alcohol, acetone, and methanol; insoluble in benzene.

2-Amino-*N*-methylbenzenesulfonamide [*16288-77-0*], $C_7H_{10}N_2O_2S$, M_r 186.23, is obtained by treating 2-nitrobenzenesulfonyl chloride with methylamine and subsequent reduction. Used as a dye component [164].

The amides of 2-aminobenzenesulfonic acid can be treated with aldehydes or orthoformic acid esters to give 1,2,4-benzothiadiazine 1,1-dioxides or their dihydro compounds; these substances have been proposed as diuretics [165].

2-Amino-*N*-(phenylsulfonyl) benzenesulfonamide, $C_{12}H_{12}N_2O_4S_2$, M_r 312.37, *mp* 193 – 194 °C, is obtained by treating 2-nitrobenzenesulfonyl chloride with benzenesulfonamide at 70 °C in the presence of aqueous sodium hydroxide solution and subsequent reduction of the nitro group [87]. Used as a component of azo dyes.

Phenyl 2-Aminobenzenesulfonate [*68227-69-0*], $C_{12}H_{11}NO_3S$, M_r 249.29, *mp* 70 °C, is obtained by treating 2-nitrobenzenesulfonyl chloride with sodium phenolate and subsequent reduction of the nitro group. Used as an azo dye component.

3-Aminobenzenesulfonic Acid (metanilic acid) [*121-47-1*], $C_6H_7NO_3S$, M_r 173.19, can be obtained by sulfonation of aniline sulfate with oleum and boric acid at 20 – 50 °C. The yield is 98 % [166].

Production. For industrial production, however, nitrobenzene is sulfonated to *m*-nitrobenzenesulfonic acid, which is then reduced either with iron [167], [168] or catalytically with hydrogen [169].

Crude 3-aminobenzenesulfonic acid can be used directly, either as a solution or dried, to obtain 3-aminophenol by alkali fusion. It is not sufficiently pure for use in dye manufacture, however. Therefore the crude solution is acidified; after filtration the product thus obtained is of satisfactory purity.

3-Aminobenzenesulfonic acid is used in the manufacture of dyes and optical brighteners [170]. It is also used to manufacture 3-hydroxybenzenesulfonic acid and 3-aminophenol. The latter is an important intermediate in the manufacture of 4-amino-2-hydroxybenzoic acid (*p*-aminosalicylic acid) used to fight tuberculosis.

3-Aminobenzenesulfonamide [*98-18-0*], $C_6H_8N_2O_2S$, M_r 172.21, *mp* 142 °C, is poorly soluble in cold water.

3-Amino-*N*-(phenylsulfonyl)benzenesulfonamide, $C_{12}H_{12}N_2O_4S_2$, M_r 312.37, is obtained by treating 3-nitrobenzenesulfonyl chloride with benzenesulfonamide and subsequent reduction of the nitro group. It is used as a dye component [171]. The use of the *N*-acrylsulfonamide in the polymerization of acrylonitrile has been proposed to improve the dyeing properties of the fibers [172].

4-Aminobenzenesulfonic Acid (sulfanilic acid) [*121-57-3*], $C_6H_7NO_3S$, M_r 173.19, is made by the reaction of aniline with sulfuric acid at temperatures above 190 °C:

Production. Equimolar amounts of aniline and sulfuric acid are reacted in a lead-lined reactor. The reaction mass is spread on trays and baked in an oven at 190 – 220 °C, the water of the reaction being removed continuously. The process is complete if a sample dissolves clearly in a dilute alkaline solution and has practically no smell of aniline. The crude product is dissolved as a sodium salt in water that has been rendered alkaline with sodium carbonate solution; traces of aniline are removed by blowing with steam. The solution is clarified by filtration and can then be processed further immediately. The baking operation can be carried out in vacuo, which facilitates the removal of the water of the reaction.

In industrial manufacture the aniline hydrogensulfate is placed on trays in trolleys and these are passed at constant speed through a tunnel-shaped oven against an air current at 260 – 280 °C. The aniline hydrogensulfate is thus brought to the baking temperature very gradually. It leaves the oven after 12.5 h [173]. According to [174] the reaction can be carried out in a fluidized bed consisting of sulfanilic acid.

The baking process can also be carried out in a multiphase reactor, with a resultant shortening of reaction time and improvement in quality of the end product [175]. The baking process can be simplified if the formation of the aniline salt and subsequent rearrangement are carried out successively or simultaneously in a solvent, e.g., diphenyl sulfone [67] or 1,2-dichlorobenzene [176]; this enables the reaction mass to be stirred throughout the production process [177]. Particularly high yield and end product purity can be achieved if the reactants are used in a molar ratio of 1 : 1; the rearrangement is carried out under a slight positive pressure (1 – 3 bar) and at 200 – 240 °C; water vapor is expelled from the reactor simultaneously [178]. The reaction time is three hours.

Analysis. The assay is carried out by diazotization. Impurities (aniline, 2,4-disulfanilic acid, 2- and 3-aminobenzenesulfonic acid) are determined by HPLC.

Uses. 4-Aminobenzenesulfonic acid is an important intermediate in the production of dyes, pesticides, pharmaceuticals, etc.

4-Aminobenzenesulfonamide [*63-74-1*], $C_6H_8N_2O_2S$, M_r 172.21, forms the basis for chemotherapeutical sulfonamides.

4-(Acetylamino)benzenesulfonic Acid [*121-62-0*], $C_8H_9NO_4S$, M_r 215.23, is produced by dissolving aminobenzenesulfonic acid in water, adding sodium carbonate, acetylating with acetic anhydride at 45 – 50 °C, and salting out with sodium chloride; the yield is 82 % [179].

4-(Acetylamino)benzenesulfonyl Chloride [*121-60-8*], $C_8H_8ClNO_3S$, M_r 233.67, *mp* 149 °C (from benzene), is relatively stable to water; therefore it can be precipitated from alcoholic solutions with water. It is freely soluble in diethyl ether and ethyl acetate; obtainable as an anhydrous product from the aqueous paste if this is subjected to azeotropic distillation with a water-immiscible solvent at a low temperature.

Production (see also [180]). Acetanilide is introduced into stirred chlorosulfuric acid solution at 20 °C. The solution is then heated to 55 °C and kept at this temperature for 1.5 h. The solution is cooled to 20 °C and introduced as a thin jet into water, the temperature of which is kept at 0 – 5 °C by external cooling. The precipitated sulfochloride is filtered and washed with cold water until neutral to Congo Red. Yield is 80 – 82 %. The crude product contains about 60 % water; the dried product melts at 144 – 147 °C. About 1 – 2 % of bis(acetylaminophenyl) sulfone is obtained as a byproduct.

If thionyl chloride is added, less chlorosulfuric acid is needed because it can be replaced partly by oleum. The product is stable for several days if kept in a cool place. It is generally used directly in the moist state. 4-(Acetylamino)benzenesulfonyl chloride is an important intermediate in the manufacture of sulfonamides and in the synthesis of parabase ester [181].

4-(Acetylamino)benzenesulfonamide [*121–61–9*], $C_8H_{10}N_2O_3S$, M_r 214.24, *mp* 219 °C, is obtained from 4-acetylaminobenzenesulfonyl chloride and aqueous ammonia at temperatures not exceeding 30 °C. Uses include the manufacture of sulfanilamide.

5-Amino-1,3-benzenedisulfonic Acid [*5294-05-3*] (**20**), $C_6H_7NO_6S_2$, M_r 253.25, is obtained by reduction of 5-nitro-1,3-benzenedisulfonic acid.

(**20**)

5-Amino-1,3-benzenedisulfonyl Chloride, $C_6H_5Cl_2NO_4S_2$, M_r 290.14, is obtained from the sodium salt or free acid with chlorosulfuric acid at 100 – 160 °C [182].

5-Amino-*N,N*-bis(2-chloroethyl)-1,3-benzene-disulfonamide [*22480-69-9*], $C_{10}H_{15}Cl_2N_3O_4S_2$, M_r 376.28, *mp* 126 – 128 °C, is formed by treating the dichloride with 2-chloroethylamine [183], [184].

4-Amino-1,3-benzenedisulfonic Acid [*137-51-9*] (**21**), $C_6H_7NO_6S_2$, M_r 253.25, crystallizes with two moles of H_2O. The compound is freely soluble in water and ethyl alcohol. It is prepared by sulfonating 4-aminobenzenesulfonic acid with oleum at 20 °C and 130 °C (4 – 6.5 h), draining the sulfonation mixture into water under pressure, adding lime at 70 – 75 °C, separating the resulting gypsum, precipitating the calcium ions with soda, removing the calcium carbonate formed, and concentrating the sodium salt solution by evaporation. Yield 90 – 91 % [185].

(**21**)

4-Amino-1,3-benzenedisulfonamide [*40642–90–8*], $C_6H_9N_3O_4S_2$, M_r 251.28, *mp* 235 °C, crystals (from water). The compound is used as a dye intermediate.

2-Amino-1,4-benzenedisulfonic Acid [*98-44-2*] (**22**), $C_6H_7NO_6S_2$, M_r 253.25, is obtained by sulfonating metanilic acid in 100 % sulfuric acid with 50 % oleum at 160 °C (5 – 6 h); the sulfonation mixture is diluted with water, lime is added, and the resulting calcium sulfate

is removed; the product is then precipitated with excess concentrated hydrochloric acid in hot solution; yield 90 – 91 % [186].

(**22**)

The trisulfonic and tetrasulfonic acids formed in this sulfonation process are unstable in hot aqueous solution. When water is added to the sulfonation mass they eliminate sulfonic acid groups, thus forming the end product; see also [187]. It is also possible to start from 4-chloro-3-nitrobenzenesulfonic acid, in which case sulfite is used to replace the chlorine by the sulfonic acid group and the resulting 2-nitro-1,4-benzenedisulfonic acid is then reduced [188].

Compound **22** is used as an intermediate for dyes; for example, see [189]. 2-Amino-1,4-benzenedisulfonic acid is converted to triazine derivatives, which are intermediates in the manufacture of dyes and optical brighteners [190], [191].

2,4-Diaminobenzenesulfonic Acid [*88-63-1*] (**23**), $C_6H_8N_2O_3S$, M_r 188.2, monoclinic plates or triclinic prisms, poorly soluble in cold water, is obtained by sulfonating a solution of *m*-phenylenediamine in 100 % sulfuric acid with oleum at 155 °C, adding water to the sulfonation mixture, desulfonating the resulting disulfonic acids at 140 °C, and isolating the free acid at 10 °C; yield 93 % [192]. Another process starts from 1-chloro-2,4-dinitrobenzene, which, as an alcoholic solution, is reacted with sodium sulfite solution to form 2,4-dinitrobenzenesulfonic acid [*89-02-1*], from which the end product is obtained by reduction with iron according to BÉCHAMP [188, pp. 99, 100].

(**23**)

4,6-Diamino-1,3-benzenedisulfonic Acid [*137-50-8*] (**24**), $C_6H_8N_2O_6S_2$, M_r 268.27, is obtained from *m*-phenylenediamine by sulfonation with excess oleum at 70 – 130 °C. Used as an intermediate for dyes [193], [194].

(**24**)

2,5-Diamino-1,4-benzenedisulfonic Acid [*7139-89-1*] (**25**), $C_6H_8N_2O_6S_2$, M_r 268.27, is obtained from *p*-phenylenediamine and 25 % oleum at 140 °C [195] or by heating *p*-phenylenediamine sulfate and 98 % sodium hydrogen sulfate in a mixture of 1,2,4-trichlorobenzene and 1-chloronaphthalene to the boiling point of the solvent mixture (215 °C), removing the solid product, dissolving it in water, neutralizing it with sodium hydroxide solution to pH 7.5 – 8, and clarifying the solution with kieselguhr. The product contains 5 % of monosulfonic acid, but only a small amount of the isomeric 2,6-disulfonic acid; yield 90 % [196]. The compound is used as an intermediate for dyes.

(**25**)

2.7. Hydroxybenzenesulfonic Acids

The chemical properties of the phenolsulfonic acids are characterized by the reactive aromatic hydroxyl group. The reactions of these acids therefore include azo coupling reactions with diazonium salts to form azo dyes. Hydroxybenzenesulfonic acids with more than one hydroxyl group on the benzene nucleus form complexes with metal ions.

2-Hydroxybenzenesulfonic Acid [*609-46-1*] (**26**), $C_6H_6O_4S$, M_r 174.17, *mp* 145 °C (mono-

hydrate); aniline salt *mp* 165 °C; potassium salt (dihydrate) *mp* 235 – 240 °C. If phenol is sulfonated with an equal amount of 100 % sulfuric acid under mild conditions, a mixture consisting of 2-hydroxy- and 4-hydroxybenzenesulfonic acid in a ratio of roughly 2 : 3 is obtained. The 2-hydroxybenzenesulfonic acid can be isolated from this mixture via the monobarium salt [197]. The pure compound is obtained by diazotizing 2-aminobenzenesulfonic acid and boiling it under acid conditions.

(**26**)

3-Hydroxybenzenesulfonic Acid [*585-38-6*] (**27**), $C_6H_6O_4S$, M_r 174.17; potassium salt (monohydrate) *mp* 200 – 210 °C; sodium salt (from ethyl alcohol) *mp* 314 °C, is synthesized by the reaction of 1,3-benzenedisulfonic acid and sodium hydroxide in water in an autoclave for 30 h at 250 °C. The reaction mass is neutralized and evaporated to dryness. The sodium salt of the acid is extracted with 78 % ethyl alcohol; yield 78 % [198]. The crude solution obtained by acidifying the reaction mass with hydrochloric acid and freeing it from sulfur dioxide by boiling can be used in the manufacture of dyes [199].

(**27**)

4-Hydroxybenzenesulfonic Acid [*98-67-9*] (**28**), $C_6H_6O_4S$, M_r 174.17, aniline salt *mp* 170 °C, *S*-benzylisothiuronium salt (monohydrate) *mp* 168.7 °C.

(**28**)

Production: phenol (25 kg) and 96 % sulfuric acid (28 kg) are heated to 50 °C; then 1.25 kg additional sulfuric acid is added and the reaction mixture is heated at 110 °C for 5 – 6 h. Reaction water, together with about 5 % of the phenol, is distilled off during this period. Yield 95 % [200].

Crude 4-hydroxybenzenesulfonic acid obtained by hot sulfonation, i.e., mixed with 2-hydroxybenzenesulfonic acid, is used as such in the manufacture of synthetic tanning agents. Condensation products of phenolsulfonic acid mixtures with formaldehyde improve the dyeing properties of polyamide fibers [201].

4-Hydroxybenzenesulfonic acid and 2-halogenomalonic esters form the corresponding ethers, which are used in the manufacture of polyesters with improved affinity for basic dyes [202].

If a mixture of hydroxybenzenesulfonic acids and bis(hydroxyphenyl) sulfone is condensed with formaldehyde, and hydrogensulfite is subsequently added, substances with good dispersing effects on dyes are obtained. They also are used as thinning agents for cement [203], [204].

Most of the 4-hydroxybenzenesulfonic acid is used as an additive for electroplating baths. By comparison, the acid is relatively unimportant as a dye intermediate. With ethylene oxide it forms poly(ethoxy)oxybenzenesulfonic acid, which can be used as a plasticizer and emulsifier.

4-Methoxybenzenesulfonic Acid

[*5857-42-1*] (**29**), $C_7H_8O_4S$, M_r 188.20, ammonium salt *mp* 285 °C. The acid is obtained by sulfonation of anisole. The ammonium salt of (**29**) can be obtained in high yield by treating anisole with an equal mass of sulfamic acid at 140 – 150 °C [205]. The compound is used in the manufacture of 4-methoxybenzenesulfonylureas, which have hypoglycemic effects.

(**29**)

4-Hydroxy-1,3-benzenedisulfonic Acid [*96-77-5*] (**30**), $C_6H_6O_7S_2$, M_r 254.24, hy-

groscopic crystals, is obtained by hydrolysis of the dichloride with ethyl alcohol and/or water. Nitration and reduction of this acid gives 5-amino-4-hydroxy-1,3-benzenedisulfonic acid. 4-Hydroxy-1,3-benzenedisulfonic acid accelerates the rearrangement of cumene hydroperoxide in the Hock – Lang phenol process [206].

(**30**)

4-Hydroxy-1,3-benzenedisulfonyl Chloride [*1892-33-7*], $C_6H_4Cl_2O_5S_2$, M_r 291.13, *mp* 89 °C, needles (from gasoline), is obtained by treating phenol with chlorosulfuric acid and introducing the sulfonation mixture into concentrated hydrochloric acid [207].

2,4-Dihydroxybenzenesulfonic Acid [*6409-58-1*] (**31**), $C_6H_6O_5S$, M_r 190.17, ammonium salt (from ethyl alcohol) *mp* 190 °C [208]. The acid is prepared by sulfonating resorcinol with 96 % sulfuric acid in a molar ratio of 1 : 1. The compound is used as a catalyst in the curing of resins [209].

(**31**)

3,4-Dihydroxybenzenesulfonic Acid [*7134-09-0*] (**32**), $C_6H_6O_5S$, M_r 190.17, deliquescent crystals; the ammonium salt (flakes, from aqueous ethanol) melts at 260 °C (decomp.). Synthesis: 0.3 mol of disodium 4-hydroxy-1,3-benzenedisulfonate is reacted with 1.2 mol of sodium hydroxide for 36 min at 340 °C; the reaction mass is diluted with water, acidified with sulfuric acid, and boiled to remove sulfur dioxide; the product is extracted with ether. Yield 80 %. Pyrocatechol is obtained by hydrolyzing the sulfonic acid group at 190 °C [210].

(**32**)

4,5-Dihydroxy-1,3-benzenedisulfonic Acid [*149-46-2*] (**33**), $C_6H_6O_8S_2$, M_r 270.23, is produced by sulfonation of pyrocatechol with oleum [211] or by alkali fusion of 2-hydroxy-1,3,5-benzenetrisulfonic acid: 10 kg of the tetrasodium salt of phenoltrisulfonic acid is introduced into 16 kg of sodium hydroxide at about 20 °C. After adding some water, the temperature is gradually raised to 160 °C; at the end of the reaction the melt is diluted with water and acidified with sulfuric acid, and sulfur dioxide is driven off. After cooling, precipitated sodium sulfate is removed by filtration and excess sulfate ions are precipitated in fractions. Finally the barium salt, which has poor solubility in cold water, is precipitated.

(**33**)

The disodium salt of **33**, which is referred to in the literature as Tiron [212], serves to detect traces of iron in blood and is used as a reagent for colorimetric determination of Ti^{4+} and Mo^{4+}. The ability to form water-soluble complex salts, e.g., with antimony, has been exploited in pharmacology [213]. Tiron is claimed to improve the storability of silver halogenide emulsions [214].

2.8. Chloro-alkylbenzenesulfonic Acids

3-Chloro-4-methylbenzenesulfonic Acid [*98-34-0*] (**34**), $C_7H_7ClO_3S$, M_r 206.65, decomposes above 110 °C. Production is from toluene by sulfonation with anhydrous sulfuric acid, followed by chlorination with gaseous chlorine [215].

(**34**)

3-Chloro-4-methylbenzenesulfonic acid is an intermediate in the manufacture of 2-chlorotoluene, 5-chloro-4-methyl-2-nitrobenzenesulfonic acid, 2,4-dichlorobenzoic acid, and 2-chloro-4-sulfobenzoic acid.

3-Chloro-4-methylbenzenesulfonyl Chloride [*42413-03-6*], $C_7H_6Cl_2O_2S$, M_r 225.09, $bp_{32\,mbar}$ 166 °C, *mp* 38 °C, is obtained by chlorination of 4-methylbenzenesulfonyl chloride in the presence of iron trichloride or antimony trichloride.

A high yield of sulfochloride with only a small percentage of isomers is obtained if toluene is sulfonated with sulfur trioxide in 1,2-dichloroethane. The resulting sulfonic acid is chlorinated in the presence of iodine, and the resulting chlorobenzenesulfonic acid is reacted with chlorosulfuric acid. The crude product can be used immediately in the production of 2,4-dichloro-α,α,α-trifluorotoluene, which is a precursor of several herbicides [216].

3-Chloro-4-methylbenzenesulfonamide [*51896-27-6*], $C_7H_8ClNO_2S$, M_r 205.66, melts at 137 °C.

5-Chloro-2-methylbenzenesulfonic Acid [*133-73-3*] (**35**), $C_7H_7ClO_3S$, M_r 206.65; the sodium salt crystallizes from water with 1/2 mol of H_2O. The acid is formed as the main product in the sulfonation of 4-chlorotoluene with 100 % sulfuric acid at 100 °C. It is purified by recrystallizing the barium salt. The compound is used in the production of 5-chloro-2-formylbenzenesulfonic acid.

(**35**)

4-Chloro-3-(trifluoromethyl)benzenesulfonyl Chloride [*32333-53-2*] (**36**), $C_7H_3Cl_2F_3O_2S$, M_r 279.06, $bp_{16\,mbar}$ 128 – 131 °C, n_D^{20} 1.5158, is obtained from 2-chloro-α,α,α-trifluorotoluene and chlorosulfuric acid in 65 % oleum [217]. The compound is used as an intermediate in the production of pesticides and dyes [217].

(**36**)

3,5-Dichloro-4-methylbenzenesulfonic Acid [*2225-18-5*], $C_7H_6Cl_2O_3S$, M_r 241.09, is obtained (in addition to tri- and tetrachlorotoluenesulfonic acids) from 4-toluenesulfonic acid by chlorination with chlorine or sulfuryl chloride in sulfuric acid [218], or by hydrolysis of the sulfonyl chloride (see next paragraph). The compound is used as an intermediate in the manufacture of 2,6-dichlorotoluene.

3,5-Dichloro-4-methylbenzenesulfonyl Chloride [*24653-79-0*], $C_7H_5Cl_3O_2S$, M_r 259.54, is formed from 4-toluenesulfonyl chloride by chlorination with chlorine, antimony trichloride being added as a catalyst [219]. The compound is used as an intermediate in the manufacture of 2,6-dichlorotoluene [218].

2.9. Amino-alkylbenzenesulfonic Acids

2-Amino-5-methylbenzenesulfonic Acid [*88-44-8*] (**37**), $C_7H_9NO_3S$, M_r 187.22, crystallizes with 1 mol of H_2O. It is produced by baking *p*-toluidine sulfate at 180 °C and 97 – 101 mbar, dissolving the product in 3 % sodium hydroxide solution, and precipitating the free acid by adding concentrated hydrochloric acid [220, 222].

(**37**)

2-Amino-3,5-dimethylbenzenesulfonic Acid [*88-22-2*] (**38**), $C_8H_{11}NO_3S$, M_r 201.24; the barium salt crystallizes from water with 2 mol of H_2O; the lead salt is very poorly soluble in water. Production is from 4-amino-1,3-dimethylbenzene (*m*-xylidine) and 96 % sulfuric acid by baking the sulfate paste in vacuo, subsequently purifying the product with boiling milk of lime, and finally precipitating the sodium salt with sodium chloride [223]. 2-Amino-3,5-dimethylbenzenesulfonic acid can also be produced by sulfonation of *m*-xylidine in 1,1,2,2-tetrachloroethane with chlorosulfuric acid and subsequent boiling until no more hydrogen chloride is formed.

(**38**)

3-Amino-4-methylbenzenesulfonic Acid [*618-03-1*] (**39**), and **5-Amino-2-methylbenzenesulfonic Acid** [*118-88-7*] (**40**), $C_7H_9NO_3S$, M_r 187.22; both compounds are produced analogously to the 3-aminobenzenesulfonic acids from the corresponding nitrotoluenesulfonic acids by Béchamp reduction.

(**39**)

(**40**)

4-Amino-3-methylbenzenesulfonic Acid [*98-33-9*] (**41**), $C_7H_9NO_3S$, M_r 187.22, crystallizes with 1 mol of H_2O. It is prepared from *o*-toluidine and 98 % H_2SO_4 via the sulfate, which is then baked. The sodium salt can be isolated after liming and precipitation of calcium sulfate [224]. The solution can be used directly in the manufacture of dyes [225].

(**41**)

4-Amino-2-methylbenzenesulfonic Acid [*133-78-8*] (**42**), $C_7H_9NO_3S$, M_r 187.22, crystallizes from water with 3 mol of H_2O. It is produced analogously to 4-amino-3-methylbenzenesulfonic acid by baking of *m*-toluidine sulfate [226].

(**42**)

2.10. Amino- and Hydroxycarboxybenzenesulfonic Acids

2-Amino-4-sulfobenzoic Acid [*98-43-1*] (**43**), $C_7H_7NO_5S$, M_r 217.2, 2,4-sulfanthranilic acid, crystallizes with 1 mol of H_2O; it is freely soluble in hot water, less soluble in cold water. The compound is obtained at a moderate yield by treating 4-methyl-3-nitrobenzenesulfonic acid with sodium hydroxide solution:

43

This acid is used mainly in the manufacture of diazoamino compounds of the R–N=N–NH–R′ type. As mixtures with naphthols these compounds have acquired importance as printing inks (Rapidogen dyes).

2-Amino-5-sulfobenzoic Acid [*3577-63-7*], (**44**) $C_7H_7NO_5S$, M_r 217.2, is produced from anthranilic acid by sulfonation with chlorosulfuric acid in anhydrous sulfuric acid or nitrobenzene or by baking the sulfate of anthranilic acid at 200 °C [227], [228]. This compound is used, like its *N*-alkyl derivatives, as a stabilizer for diazo compounds (see next paragraph).

(**44**)

2-Isobutylamino-5-sulfobenzoic Acid, $C_{11}H_{15}NO_5S$, M_r 273.31, is obtained in crystalline form by sulfonating *N*-isobutylanthranilic acid in 98 % sulfuric acid with 65 % oleum at 80 °C and pumping the sulfonation mixture into water; yield 93 – 94 % [229].

2-Hydroxy-5-sulfobenzoic Acid [*97-05-2*] (**45**), $C_7H_6O_6S$, M_r 218.18, needles, *mp* 120 °C, soluble in water, ethyl alcohol, and ether, is obtained by heating one part of salicylic acid with 5 parts of concentrated sulfuric acid [230]. It can also be prepared from the sulfochloride.

(**45**)

2-Hydroxy-5-sulfobenzoic acid forms a dihydrate and is used in analytical chemistry to detect albumins, iron, and mercury [231]. Applications described in patents include the use as a heat stabilizer for polyacrylonitrile [232], as an additive used in the anodizing of metals [233–235], and – as a tributyltin compound – as an agent for the antibacterial protection of organic materials [236]. The acid is also claimed to be suitable for a pregnancy test for horses [237].

5-(Chlorosulfonyl)-2-hydroxybenzoic Acid [*17243-13-9*], $C_7H_5ClO_5S$, M_r 236.63, *mp* 171 °C (decomp.), is obtained from salicylic acid and chlorosulfuric acid [238], [239]. The compound is used to manufacture the corresponding sulfinic acid and sulfones.

2.11. Chloro-hydroxybenzenesulfonic Acids

3-Chloro-4-hydroxybenzenesulfonic Acid [*46060-27-9*] (**46**), $C_6H_5ClO_4S$, M_r 208.62, is prepared by chlorination of 4-hydroxybenzenesulfonic acid or by sulfonation of 2-chlorophenol with 98 % sulfuric acid [240]. The compound can be converted by nitration into 3-chloro-4-hydroxy-5-nitrobenzenesulfonic acid, from which 3-amino-5-chloro-4-hydroxybenzenesulfonic acid is obtained by reduction. The sulfonic acid group is eliminated easily at 180 – 190 °C.

(**46**)

5-Chloro-2-hydroxybenzenesulfonic Acid [*2051-65-2*] (**47**), $C_6H_5ClO_4S$, M_r 208.62, is obtained from 2,5-dichlorobenzenesulfonic acid by partial hydrolysis with sodium hydroxide solution in water at 170 – 190 °C and precipitation with concentrated hydrochloric acid. Used to prepare 5-chloro-2-hydroxy-3-nitrobenzenesulfonic acid, which is then reduced to 3-amino-5-chloro-2-hydroxybenzenesulfonic acid.

(**47**)

3,5-Dichloro-2-hydroxybenzenesulfonic Acid [*26281-43-6*] (**48**), $C_6H_4Cl_2O_4S$, M_r 243, forms a poorly water-soluble barium salt.

(**48**)

3,5-Dichloro-2-hydroxybenzenesulfonamide [*35337-99-6*], $C_6H_5Cl_2NO_3S$, M_r 242.08, melts at 230 °C. It is obtained from the chlorosulfonation of 2,4-dichlorophenol and conversion with ammonia or NH_4Cl. It can be used as a precursor to synthesize some 2-hydroxybenzenesulfonamides that are poorly accessible by other routes, by dehalogenation with H_2 and Pd/C catalyst [241].

2.12. Aminohydroxybenzenesulfonic Acids and Aminochlorohydroxybenzenesulfonic Acids

All the compounds described in this section are used in the manufacture of dyes.

3-Amino-4-hydroxybenzenesulfonic Acid [*98-37-3*] (**49**), $C_6H_7NO_4S$, M_r 189.19, is freely soluble in hot water, slightly soluble in cold, dilute hydrochloric acid. Obtained by boiling 4-chloro-3-nitrobenzenesulfonic acid with sodium hydroxide solution, followed by Béchamp reduction [242]:

49

3-Amino-4-hydroxybenzenesulfonic acid is an important intermediate in the production of dyes and is used to manufacture Diamond Black PV and 3-amino-4-hydroxy-5-nitrobenzenesulfonic acid.

3-Amino-4-hydroxybenzenesulfonamide [*98-32-8*], $C_6H_8N_2O_3S$, M_r 188.2. Manufacture: 2-nitrochlorobenzene is sulfochlorinated with chlorosulfuric acid; the resulting sulfochloride is treated with ammonia to give 4-chloro-3-nitrobenzenesulfonamide; chlorine is replaced by hydroxyl by heating the product at 100 °C in aqueous sodium hydroxide solution. Finally, the hydroxybenzenesulfonamide is reduced with iron turnings [243].

3-Amino-4-methoxybenzenesulfonic Acid [*98-42-0*] (**50**), $C_7H_9NO_4S$, M_r 203.22, needles, is freely soluble in water. The compound is obtained from 2-anisidine and 98 % sulfuric acid at 50 – 55 °C [244].

(**50**)

3-Acetylamino-4-methoxybenzenesulfonyl Chloride [*3746-67-6*] (**51**), $C_9H_{10}ClNO_4S$, M_r 263.7, *mp* 152 – 163 °C, is obtained from 2-acetylaminoanisole and chlorosulfuric acid at 35 – 40 °C [245–247]. The compound is used to produce the corresponding sulfinic acid and Fast Red ITR base.

(**51**)

3-Acetylamino-4-methoxybenzenesulfonamide [*85605-29-4*], $C_9H_{12}N_2O_4S$, M_r 244.27, melts at 226 °C.

3-Acetylamino-4-methoxy-*N*-methylbenzenesulfonamide, $C_{10}H_{14}N_2O_4S$, M_r 258.3, is obtained by treating the chloride with 2 mol of ethylamine at 25 °C. Other *N*-alkylamides of this sulfonic acid are produced in the same way [248].

5-Amino-4-hydroxy-1,3-benzenedisulfonic Acid [*120-98-9*] (**52**), $C_6H_7NO_7S_2$, M_r 269.25, is obtained by nitration of 4-hydroxy-1,3-benzenedisulfonic acid and reduction of the hydroxynitrobenzenedisulfonic acid [84, p. 148].

(**52**)

5-Acetylamino-2-hydroxybenzenesulfonic Acid [*55034-25-8*] (**53**), $C_8H_9NO_5S$, M_r 231.23, needles, freely soluble in water, decomposition on melting. Manufactured by sulfonating *N*-(4-hydroxyphenyl)acetamide with 98 % sulfuric acid at 80 °C [249] or by acetylating 5-amino-2-hydroxybenzenesulfonic acid with acetic anhydride and sodium acetate in water.

(**53**)

3-Amino-6-ethoxybenzenesulfonic Acid [*6375-02-6*] (**54**), $C_8H_{11}NO_4S$, M_r 217.24, needles, poorly soluble in water and ethyl alcohol. Manufactured by treating *o*-dichlorobenzene with 96 % sulfuric acid and baking the resulting sulfate or from phenetidine by reaction with oleum [250].

(**54**)

4-Amino-6-methoxy-1,3-benzenedisulfonic Acid (**55**), $C_7H_9NO_7S_2$, M_r 283.28.

(**55**)

4-Amino-6-methoxy-1,3-benzenedisulfonyl Chloride [*670-02-0*], $C_7H_7Cl_2NO_5S_2$, M_r 320.17, *mp* 129 – 130 °C, is obtained by adding sodium chloride to *m*-anisidine and chlorosulfuric acid while cooling with ice and then heating [251].

3-Amino-5-chloro-2-hydroxybenzenesulfonic Acid [*88-23-3*] (**56**), $C_6H_6ClNO_4S$, M_r 223.63, colorless crystals, freely soluble in hot water, less soluble in cold water, very easily soluble in sodium hydroxide solution. The industrial product has a weak brownish-pink color and is produced by sulfonating 2-amino-4-chlorophenol or from *p*-chlorophenol:

56

The 5-chloro-2-hydroxy-3-nitrobenzenesulfonic acid obtained from *p*-chlorophenol by sulfonation and nitration is reduced with iron and hydrochloric acid without being precipitated. After filtering from the iron sludge, the highly alkaline reduction liquor is concentrated by evaporation and decolorized with activated carbon. Upon acidification 3-amino-5-chloro-2-hydroxybenzenesulfonic acid precipitates. Yield 72 %, based on *p*-chlorophenol. The acid is an important intermediate for dyes. It is used mainly in the manufacture of Diamond Black P 2 B and of acid chrome blue dyes.

3-Amino-5-chloro-4-hydroxybenzenesulfonic Acid (**57**) is similar in properties and manufacture to 3-amino-5-chloro-2-hydroxybenzenesulfonic acid but is less important industrially [252].

(**57**)

2.13. Amino-chlorobenzenesulfonic Acids

2-Amino-5-chlorobenzenesulfonic Acid [*133-74-4*] (**58**), $C_6H_6ClNO_3S$, M_r 207.64, decomposes at 280 °C and crystallizes from water with 1 mol of H_2O. Manufactured by baking 4-chloroaniline hydrogensulfate in vacuo; after the mass has been pumped into water, the acid is neutralized with calcium oxide; the solution is suitable for use in the manufacture of azo dyes [253].

(**58**)

3-Amino-4-chlorobenzenesulfonic Acid [*98-36-2*] (**59**), $C_6H_6ClNO_3S$, M_r 207.64, needles (from water), crystallizes with 1 mol of H_2O. It is obtained from 4-chloro-3-nitrobenzenesulfonic acid by reduction; the compound is used for the production of azo dyes.

(**59**)

2-Amino-4,5-dichlorobenzenesulfonic Acid [*6331-96-0*] (**60**), $C_6H_5Cl_2NO_3S$, M_r 242.08, crystallizes as needles from water. Manufactured by baking 3,4-dichloroaniline sulfate. The compound is used as a component of azo dyes.

(**60**)

2-Amino-4,5-dichlorobenzenesulfonyl Chloride [*36110-12-0*], $C_6H_4Cl_3NO_2S$, M_r 260.53, is obtained by treating 3,4-dichloroaniline with chlorosulfuric acid in the presence of sodium chloride.

2-Amino-4,5-dichlorobenzenesulfonamide [*16948-63-3*], $C_6H_6Cl_2N_2O_2S$, M_r 241.1, *mp* 183 – 185 °C, crystals from 50 % alcohol, is obtained by treating the chloride with aqueous ammonia [254].

4-Amino-2,5-dichlorobenzenesulfonic Acid [*88-50-6*] (**61**), $C_6H_5Cl_2NO_3S$, M_r 242.08, is obtained by sulfonating 2,5-dichloroaniline with 65 % oleum in anhydrous sulfuric acid; the compound is purified via the sodium salt [255].

(**61**)

4-Amino-6-chloro-1,3-benzenedisulfonic Acid (**62**), $C_6H_6ClNO_6S_2$, M_r 287.7.

(**62**)

4-Amino-6-chloro-1,3-benzenedisulfonyl Chloride [*671-89-6*], $C_6H_4Cl_3NO_4S_2$, M_r 324.59, *mp* 142 – 144 °C, is obtained by chlorosulfonation of 3-chloroaniline with 11 mol of chlorosulfuric acid at 130 °C [256–258]; after the chlorosulfonation mixture is treated with 4 mol of thionyl chloride at 80 °C, the yield is 90 % [259].

4-Amino-6-chloro-1,3-benzenedisulfonamide [*121-30-2*], $C_6H_8ClN_3O_4S_2$, M_r 285.73, *mp* 258 – 260 °C, is obtained by treating the chloride with ammonia in *tert*-butanol and concentrating the solution by evaporation; the yield is 80 % [259]. Condensation with formic acid gives 6-chloro-7-sulfamoyl-1,2,4-benzothiadiazine 1,1-dioxide, an important diuretic [260], [261]. The 1-monoamide **63** is an intermediate for the production of azo dyes for polyamide fibers. For manufacture, see [262].

(**63**)

4-Amino-6-chloro-N^1,N^2-dimethyl-1,3-benzene-disulfonamide [*60385-32-2*], $C_8H_{12}ClN_3O_4S_2$, M_r 313.78, *mp* 183 °C (crystals from aqueous alcohol), is prepared by boiling the chloride with aqueous methylamine in dioxane at reflux temperature for 3 h and precipitating with water [256].

2.14. Amino-chloro-alkylbenzenesulfonic Acids

2-Amino-5-chloro-4-methylbenzenesulfonic Acid [*88-53-9*] (**64**), $C_7H_8ClNO_3S$, M_r 221.66, is a colorless to slightly reddish crystalline powder. The compound is obtained by chlorination of *p*-toluenesulfonic acid to form 3-chloro-4-methylbenzenesulfonic acid, subsequent nitration of this acid to a mixture of nitro isomers, precipitation of the 2-chloro-4-methyl-6-nitrobenzenesulfonic acid with sodium chloride solution, and, finally, Béchamp reduction of the nitro group with iron and acetic acid [263].

A different synthesis route in which no isomers are formed is as follows [264]:

64

The compound is used as Lake Red C and CLT Acid as a diazo component for azo dyes and azo pigments.

3-Amino-5-chloro-4-methylbenzenesulfonic Acid [*6387-27-5*] (**65**), $C_7H_8ClNO_3S$, M_r 221.66, is a moist, slightly reddish paste in raw form. It is manufactured by sulfonation of 1-chloro-2- methyl-3-nitrobenzene [*83-42-1*] with oleum, followed by Béchamp reduction [265]. The compound is used as a diazo component for azo dyes in the dyeing of leather.

(**65**)

4-Amino-5-chloro-3-methylbenzenesulfonic Acid [*6387-14-0*] (**66**), $C_7H_8ClNO_3S$, M_r 221.66, needles from water, splits off the sulfonic acid group in 75 % sulfuric acid at

150 – 160 °C. It is made by sulfonation of 2-chloro-6-methylaniline in *o*-dichlorobenzene with anhydrous sulfuric acid in vacuo, during which the water of the reaction distills off [266]. Alternative: chlorination of 4-acetylamino-3-methylbenzenesulfonic acid in water and deacetylation. The compound is used as a dye component.

(**66**)

4-Amino-5-chloro-2-methylbenzenesulfonic Acid (**67**), $C_7H_8ClNO_3S$, M_r 227.66, is obtained from *m*-toluidine sulfate by chlorination, followed by sulfonation in an inert solvent [267].

(**67**)

2-Amino-4-chloro-5-methylbenzenesulfonic Acid [*88-51-7*] (**68**), $C_7H_8ClNO_3S$, M_r 221.66, is insoluble in cold water. The compound is made by baking 3-chloro-4-methylbenzeneamine hydrogensulfate in vacuo at 195 °C [268], and it is used for dyes; see, for example, [269].

(**68**)

6-Amino-2,4-dichloro-3-methylbenzenesulfonic Acid (**69**), $C_7H_7Cl_2NO_3S$, M_r 256.11, is obtained by sulfonation of 3,5-dichloro-4-methylaniline in *o*-dichlorobenzene with chlorosulfuric acid [270].

1. Introduction

Benzidine [*92-87-5*], 4,4′-biphenyl-diyldiamine, and its substitution products represent the group called the diphenyl bases. They are used mainly as intermediates in the production of azo dyes and azo pigments. Symmetrically or asymmetrically coupled products can be produced by simultaneous or successive diazotization (coupling), respectively.

The diphenyl bases Benzidine have aroused interest as cross-linking agents, e.g., in polyurethane plastics [10], in which they can noticeably increase the temperature stability [11]. The diphenyl radical has a chain-stiffening effect in polyamides [12]. The ability of the diphenyl bases to react with numerous cations, anions, and organic substances, such as oxidizing agents and blood, is utilized for analytical and diagnostic purposes.

The economic importance of the diphenyl bases is apparent from the fact that world production in 1983 was about 15 kt. The major producing countries were the United States, Japan, and the Federal Republic of Germany.

The most important of the diphenyl bases are *o*-tolidine, 3,3′-dichlorobenzidine, and *o*-dianisidine. The physical and chemical properties of benzidine and its derivatives are treated in detail in Chapter 6. The following sections describe the general methods for the production and handling of benzidine and benzidine derivatives.

2. Production

Benzidine and the other diphenyl bases are produced in three separate processing stages:

1) Reduction of nitro groups to form hydrazo compounds
2) Benzidine rearrangement
3) Isolation of the bases

2.1. Reduction

The alkaline reduction of nitrobenzene to hydrazobenzene can be represented by the simple equation

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a03_539

$$2\,C_6H_5NO_2 + 10\,H \longrightarrow C_6H_5NH\text{–}NHC_6H_5 + 4\,H_2O$$

It passes, according to the Haber process, through several stages, including the intermediate condensation of a nitroso with a hydroxylamine compound to form the azoxy compound.

This method always forms symmetrical hydrazo compounds.

The main byproduct is the monocyclic primary amine (e.g., aniline) corresponding to the original nitro compound. This is formed not only by further reduction of the phenylhydroxyamine, but also by disproportionation of the unstable hydrazo compound.

Various reduction methods are used in industry.

Reduction with Zinc Dust. The reduction of aromatic nitro compounds with zinc dust in alkaline medium takes place according to the equation:

$$2\,C_6H_5NO_2 + 5\,Zn + 10\,NaOH \longrightarrow C_6H_5NH\text{–}NHC_5H_5 + 5\,Na_2ZnO_2 + 4\,H_2O$$

In industry, the nitro compound is reduced in batches of 500 kg or more. The nitro compound is dissolved in a high-boiling solvent, e.g., *o*-dichlorobenzene or solvent naphtha, and alcohols (methanol, ethanol) are often added to keep the resultant hydrazo compound in solution. Zinc dust is then suspended in this solution and sodium hydroxide solution is emulsified with it. A quantity of zinc dust as much as 50 % above the theoretical requirement is usually needed. The necessary alkali is introduced in the form of a concentrated (40 – 50 %) sodium hydroxide solution. Only a small percentage (ca. 2 – 10 %) of the theoretical quantity of sodium hydroxide is required because the sodium zincate quickly regenerates alkali by hydrolysis.

$$Na_2ZnO_2 + H_2O \longrightarrow 2\,NaOH + ZnO$$

The reduction is highly exothermic. It can be regulated by controlling the addition of one or more of reactants. The optimum reduction temperature is between 80 and 120 °C, depending on the aromatic compound. Higher temperatures can be used with the unsubstituted nitrobenzene without causing overreduction than are possible with *o*-alkyl and *o*-alkoxy nitrobenzenes. In many cases the addition of small amounts of zinc dust and water is necessary to complete reduction and convert zinc oxide into zinc hydroxide.

The reduction is terminated when the red color of the azo stage has disappeared. The hydrazobenzene solution is then separated, either directly or after dilution with hot water, from the zinc hydroxide, which may still contain unconverted zinc dust. The zinc hydroxide is extracted with fresh solvent to increase the yield. The hydrazobenzene solutions are usually subjected to a subsequent benzidine rearrangement without intermediate isolation of the hydrazo compound. The zinc hydroxide is freed of solvent in a vacuum or with steam and either further processed into zinc salts or dried and returned to the zinc works [13], [14]. The reduction process using zinc and alkali is technically the most important and can be used for all hydrazo compounds.

However, because of the high price of zinc dust there have been numerous attempts to replace it with cheaper reducing agents.

Reduction with Iron. Reduction with iron and sodium hydroxide solution, only of minor importance in preparative chemistry, has been investigated extensively for commercial production ever since 1900.

$$2\,C_6H_5NO_2 + 4\,Fe + 6\,H_2O \longrightarrow C_6H_5NH\text{–}NHC_6H_5 + 2\,Fe(OH)_2 + 2\,Fe(OH)_3$$

Finely ground cast iron turnings, iron powder obtained by decomposition of iron carbonyl, carbide-containing iron, or ferrosilicon are used. The iron turnings are first slightly corroded with 60 % sodium hydroxide solution. To prevent overreduction the concentration of sodium hydroxide is maintained at a high level and sometimes even increased during reduction. Reduction is carried out using nitrobenzene, iron, and

sodium hydroxide in the molar ratio 1 : 2 : 4 at a temperature of 100 – 120 °C.

The process can be used for the reduction of nitrobenzene to hydrazobenzene but less often for its substitution products, especially because it is difficult to separate the hydrazo compound from the ferruginous mud. A yield of 88 – 92 % has been reported for the reduction of nitrobenzene to hydrazobenzene using ferrosilicon (15 % Si) [14].

Reduction with Sodium Amalgam. Sodium amalgam at 70 – 100 °C in an upright, cylindrical nickel reactor is brought into contact with nitrobenzene emulsified in water or sodium hydroxide. The process is carried out in batches to produce azobenzene. The reduction conditions can be varied by adding solvent (solvent naphtha), changing the concentration of the sodium hydroxide solution or the amalgam, or by adding decomposition catalysts (graphite, activated charcoal).

Nevertheless, in the further reduction from the azo to the hydrazo stage, some overreduction to the monocyclic amine cannot be avoided. The product formed contains up to 90 % azobenzene in addition to hydrazobenzene, aniline, and nitrobenzene. It is therefore isolated and further reduced to the hydrazo stage with zinc dust and sodium hydroxide solution. The amalgam reduction is used industrially only with unsubstituted nitrobenzene.

Electrolytic Reduction. The electrochemical reduction of nitro to hydrazo compounds is also carried out on a commercial scale.

$$2\,C_6H_5NO_2 + 10\,H^+ + 10\,e^- \longrightarrow C_6H_5NH\text{–}NHC_6H_5 + 4\,H_2O$$

Electrolytic cells, with cathodes, diaphragms, and anodes positioned either side by side or above each other, are used.

The satisfactory functioning of electrolytic reduction depends largely on the condition of the surface of the cathode. Sheet iron cathodes with a lead sponge are used. Overreduction is less likely to occur with a lead sponge than with shiny lead surfaces. Even lead cathodes with spongy zinc have been used, but the spongy zinc was partially used up by chemical reduction. Nickel cathodes have also been described [14], [15].

The catholyte consists of a vigorously stirred emulsion of the nitro compound in 8 – 10 % sodium hydroxide solution. Ethanol and toluene can be used as diluents. Depending on the geometry of the cell, solvents with high specific gravities (chlorinated benzene, chlorinated toluene, or chlorinated naphthalene) are used to keep the cathode liquid away from the anode compartment above it. Cement or special ceramic compounds are used to make the diaphragms. The anolyte, consisting of 10 % sodium hydroxide solution, contains the lead or iron anode, which has a PbO_2 coating or, for preparative purposes, may also be nickel-plated.

Electrochemical reduction is carried out at temperatures of 65 – 90 °C, current densities of about 20 A/dm^2 and voltages of 4 – 10 V. Electrochemical reduction is technically satisfactory and may also be cheaper than zinc dust reduction if it is interrupted when only about 50 % of the starting material has reached the hydrazo stage. After rearrangement and separation of the diphenyl base salts, the azo components and the solvent are recovered for the next batch. Nitrobenzene, 2-chloronitrobenzene, 2,5-dichloronitrobenzene, 2-nitrotoluene, and 2-nitroanisol can be electrochemically reduced to hydrazo compounds in yields of 70 – 90 % [14], [15].

Catalytic Reduction. Nitrobenzene can be reduced to hydrazobenzene with hydrogen in the presence of a palladium–carbon catalyst. Industrially, reduction is carried out in dilute alcohol (ethyl or isopropyl alcohol) in the presence of a base, such as 50 % sodium hydroxide solution. The reaction takes place in an autoclave at 80 – 85 °C and with a slightly elevated pressure. Overreduction is suppressed by the high concentration of alkali. The yield can also be influenced by buffering the reaction medium, e.g., by the addition of acetates, borates, or alkanolamines. This reduction method also applies to 2-nitrotoluene and 2-nitroanisol.

For preparative purposes, Raney nickel can be used at elevated temperatures and with mixed catalysts. Instead of hydrogen, hydrazine hydrate or sodium borohydride can be used with palladium – calcium carbonate, Raney nickel, ruthenium – carbon, or copper ions as the catalyst [14].

Other Reduction Methods. In preparative chemistry, numerous other reducing agents are used to produce hydrazo compounds. Lithium, sodium, potassium, magnesium, and aluminum are used for reduction, either as metals or as alcoholates. Silicon, lithium, and aluminum are used as amalgams. Of the nonmetal reducing agents, special mention should be made of hydrogen sulfide and its salts (sulfide reduction). Methanol, formaldehyde, and glucose, sometimes combined with quinonoid catalysts, are organic reducing agents.

2.2. Benzidine Rearrangement

Aromatic hydrazo compounds, formed by the alkaline reduction of aromatic nitro compounds, are easily rearranged by mineral acids into diaminodiphenyl compounds (**1**) – (**3**) and aminodiphenylamine compounds (**4**), (**5**). This is the second stage in the production of diphenyl bases.

Hydrazobenzene Benzidine (1)

Traces of *o*-benzidine (2,2′-diaminodiphenyl) (**2**) are formed as a byproduct by ortho rearrangement, and diphenyline (2,4′-diaminodiphenyl) (**3**) is also formed in appreciable quantities by ortho-para rearrangement.

2 3

Partial rearrangements yield *o*-semidine (2-aminodiphenylamine) (**4**) and *p*-semidine (4-aminodiphenylamine) (**5**).

4 5

The type and quantity of the rearrangement products are largely dependent on the chemical constitution of the reactant and can only be influenced to a limited extent by the reaction conditions. The byproducts, mainly diphenyline (**3**), are formed in quantities of up to 15 % and have no commercial value.

The benzidine rearrangement is a true intramolecular reaction because no mixed benzidines are formed from mixtures of different hydrazo compounds and because only the corresponding unsymmetrical benzidine is obtained from unsymmetrically substituted hydrazobenzenes [16].

The industrial benzidine rearrangement usually starts with the hot solution that is obtained from the reduction of the nitro compound to the hydrazo compound. Intermediate isolation of the hydrazo compound is not necessary, but it is advisable in some cases, such as amalgam reductions. Because hydrazo compounds disproportionate to form azo compounds and the corresponding monocyclic amines at higher temperatures, some reducing agent, such as sodium hydrosulfite (sodium dithionite) or zinc dust, can be added to reduce the azo content of the hydrazo compound.

$$2\,C_6H_5NH\text{–}NHC_6H_5 \longrightarrow C_6H_5N{=}NC_6H_5 + 2\,C_6H_5NH_2$$

The hydrazo solution is mixed with a mineral acid in an acid-resistant mixer. Depending on the substituents, suitable mineral acids are 10 – 30 % hydrochloric acid, 20 – 80 % sulfuric acid, or a mixture of these two. The optimum rearrangement temperature varies from 0 – 5 °C for dianisidine to 100 °C for the less heat-sensitive diphenyl bases. Temperatures higher than necessary diminish the yield, which should be 70 – 95 %.

2.3. Isolation

The most important stage of the benzidine rearrangement is the formation of a hydrochloric or sulfuric acid salt of the diphenyl base. This is either isolated directly, e.g., by salting out with sodium chloride or sodium sulfate, or first converted into the free base. For this a dilute alkali, such as sodium hydroxide solution or ammonia solution, should be used. The undesirable byproducts, especially the monocyclic amine and diphenyline, can be separated out relatively easily because of the greater solubility of these bases and their salts. Finally, only the azo compound remains in the inert solvent after acid extraction. It is returned to the reduction process along with the solvent.

3. Storage and Transportation

The diphenyl bases and their salts are usually introduced onto the market in the form of moist solids to prevent dust from forming when they are handled. They are packed in corrugated-iron drums with plastic liners; in addition, plastic-lined fiber drums, which can be burnt after they have been emptied and rinsed out, are often used as disposable packs. Wooden drums are avoided. The packs should be kept closed if possible so that dust does not form as a result of drying out of the diphenyl bases.

Benzidine is often isolated by collecting it on suction filters as a slurry and then transporting it in this form. The earlier procedure of drying, distilling, and grinding diphenyl bases is no longer used.

If the diphenyl bases are to be further processed by the producer in an integrated system, they are transported through pipe systems as aqueous suspensions.

4. Occupational Health

4.1. General Safety Precautions

Benzidine has properties which are dangerous to health and the health effects of the substituted diphenyl bases are unknown. The diphenyl bases should therefore be produced and processed in special, separated areas. Walls and floors must not be capable of absorbing chemicals. The floors should have adequate drainage and wood should not be used either as a building material or for equipment. Good ventilation must be ensured and provisions must be made for air circulation. Ventilation of the workrooms must not be restricted. The exhaust air must be effectively cleansed using filters or exhaust-gas scrubbers. Wherever possible, equipment should operate as a closed system. Filter presses and open suction filters must be avoided. A vacuum in the system is a precaution against leakage or the uncontrolled escape of vapors. When evacuated machines are opened, attention must be paid to the formation of sublimates. Tasks that involve an increased risk of human contact include sampling during manufacturing and processing, isolation, packing, and filling. If possible, the work is carried out with automated machines or in separately ventilated areas. Before undertaking repairs, special care must be taken to ensure that the equipment has been decontaminated.

Scalding out should only be allowed if the vapors can be carefully condensed and do not enter the atmosphere. If necessary and if permitted by the construction material, purification can be carried out by the addition of chemicals. Reaction with hypochlorite or even diazotization is suitable for the chemical destruction of amines. When using dilute hypochlorite solution, care must be taken to ensure that the solution is always kept considerably basic by the appropriate addition of alkali. This avoids formation of explosive nitrogen trichloride. Access to contaminated containers should only be permitted if complete protective clothing is worn and breathing apparatus is used. Diphenyl bases penetrate the surface of protective articles made of rubber or plastic. The workplaces must be monitored for emissions of benzidine and its derivatives [17].

4.2. Special Safety Regulations

In the United States and most other industrialized countries, rules and regulations have been issued for benzidine, which is regarded as carcinogenic in humans, and for 3,3′-dichlorobenzidine, which has proved to be carcinogenic in animals [18]. The aim is to protect the worker from contamination. Mixtures containing 0.1 wt% or more of benzidine are subjected to detailed handling regulations. The production of benzidine and its salts is prohibited in Japan and has been stopped in the Soviet Union.

Nowadays the most commonly produced and used diphenyl base is 3,3′-dichlorobenzidine (as the free base or one of its salts). The appropriate U.S. regulations are therefore presented. They apply to substances that contain at least 1 wt% 3,3′-dichlorobenzidine or its salts [19].

1) Areas in which these substances are produced, processed, used, repackaged, released, handled, or stored are designated *controlled areas.*
2) The number of people entering and leaving these areas must be restricted and monitored. In these areas a distinction is made between
   a) isolated systems, e.g., glove boxes

b) closed systems, e.g., sealed containers or piping systems
Special permission must be obtained for access to closed systems; employees shall be required to wash themselves upon each exit from the regulated areas.
c) open vessel system operations are prohibited.

3) Upon completion of their work in isolated or closed systems, employees must observe certain minimum regulations in terms of personal hygiene.
4) When opening a system employees shall be required to wear clean, full-body protective clothing, shoe covers, and gloves. Employees engaged in 3,3′-dichlorobenzidine (or its salts) handling operations shall be required to use a half-face filter-type respirator for dusts, mists, and fumes.
5) For the cleanup of leaks or spills and maintenance or repair operations on contaminated systems, impervious garments, gloves, boots, and a hood with a continuous supply of air should be worn.
6) Prior to each exit from a regulated area, employees shall be required to remove and leave behind protective clothing and to place used clothing and equipment in impervious containers for purposes of decontamination or disposal.
7) Employees shall be required to wash on each exit from the regulated area and to shower after the last exit of the day.
8) A daily roster of employees entering regulated areas shall be established and maintained. Before taking up employment they must be informed of the carcinogenic hazard of 3,3′-dichlorobenzidine, of the possibilities of contact with the product in their work, and of the medical surveillance program. They are subjected to an annual medical examination.
9) Signs bearing the following inscription should be posted at the entry points of regulated areas:
CANCER-SUSPECT AGENT
AUTHORIZED PERSONNEL ONLY
10) More detailed warnings apply to contaminated areas. Additional signs should inform employees of the procedures that must be followed upon entering or leaving a regulated area.
11) The storage, consumption, and use of foodstuffs, drinks, tobacco, cosmetics, and the like are prohibited in regulated areas.
12) Decontamination procedures shall be established. Dry sweeping and dry mopping are prohibited.
13) The contents of the containers must be identified by suitable labels. The words *Cancer-Suspect Agent* must be added, the minimum size print being stipulated.
14) Any incidents must be reported to the relevant authorities.
15) Deposits on machinery or parts of the building are detected by a swipe test. Sodium hypochlorite solution must be used for decontamination.

In Great Britain the use (for research purposes) of *Prohibited Substances*, such as benzidine and its salts, is only possible if special permission is obtained for work in completely closed systems or if the benzidine, in the form of a hydrochloride, is always kept moist with at least one part water to two parts benzidine hydrochloride.

Dichlorobenzidine, *o*-tolidine, *o*-dianisidine, and their salts are designated *Controlled substances*, and employees should be protected from contamination by these substances. Workers are medically monitored and records kept [20].

In the Federal Republic of Germany the important diphenyl bases are included among the regulated dangerous working substances.

1) Benzidine and its salts are regarded as carcinogenic hazards in concentrations above 0.01 % by weight in the working material.
2) 3,3′-Dichlorobenzidine is regarded as a carcinogenic hazard in concentrations above 0.1 % by weight in the working material.
3) *o*-Tolidine is considered harmful to health.
4) *o*-Dianisidine and its salts are considered toxic.

When working with these substances, all the necessary measures relating to safety, industrial medicine, and occupational hygiene should be taken to protect employees from the effects of these substances and to keep their health under constant medical check. The air at the workplace should be examined to monitor the benzidine

and 3,3′-dichlorobenzidine contents. If benzidine or 3,3′-dichlorobenzidine is marketed, the package must bear the words *May cause cancer* [21].

Equipment in which benzidine or its salts may be present must be operated in such a way that breakdowns are prevented and the harmful effects are kept to a minimum. All the necessary precautions are summarized in [22].

In accordance with the technical regulations for dangerous working substances, the presence of an effect must always be assumed when handling benzidine. Here "effect" means the risk of damage to workers' health. If the concentration of 3,3′-dichlorobenzidine in the air is below 0.1 mg/m^3 at the workplace, it can be assumed to have no effect on the worker [23].

In Belgium [24], Japan [25], and numerous other countries there are similar regulations for handling benzidine and its derivatives [26]. Before starting a job in which diphenyl bases can be formed or are used, it is high advisable to obtain exact details of the local regulations.

5. Environmental Protection

The acute fish toxicity LC_{50} is about 5 – 50 ppm, depending on the type of fish and the diphenyl base. In terms of acute toxicity, diphenyl bases can be regarded as only slightly toxic to mammals. The oral LD_{50} for rats is 3820 mg/kg for 3,3′-dichlorobenzidine, 404 mg/kg for *o*-tolidine, and 1920 mg/kg for *o*-dianisidine.

Benzidine achieves only a slight, and 3,3′-dichlorobenzidine a moderate bioaccumulation in bluegill sunfish [27]. Thus benzidine is unlikely reach a significant level in the food chain [28].

Because of the very low vapor pressures of the diphenyl bases, emissions into the ambient air from production or processing works are only possible in the form of dust. Such emissions can certainly be prevented by filtering or by using wet separators. Diphenyl base concentrations in the ambient air are monitored using TLC or HPLC [29].

In aqueous solution 3,3′-dichlorobenzidine base is very quickly degraded by photolysis, with monochlorobenzidine and benzidine being formed as intermediates [30], [31]. 3,3′-Dichlorobenzidine, *o*-tolidine, and *o*-dianisidine can be slowly biodegraded. More than 90 % of these two compounds can be eliminated in biological waste water treatment plants. Elimination takes place mainly by adsorption on sediments followed by slow biodegradation. Only a portion can be extracted again. This part declines as the adsorption process continues, because the 3,3′-dichlorobenzidine reacts with the sediments [30].

3,3′-Dichlorobenzidine cannot be removed quantitatively from waste water by hypochlorite solution because higher chlorinated benzidines are formed. Tetrazotization and conversion into 3,3′-dichloro-4,4′-dihydroxybiphenyl are more suitable procedures; they reduce the 3,3′- dichlorobenzidine content to less than 0.1 mg/kg [32]. Other appropriate waste water purification processes are oxidation with peroxide, adsorption on suspended adsorption agents, precipitation with iron(III) hydroxide, and combinations of these methods.

For decontamination of workrooms, buildings, and machines, a hot solution of 5 wt% tetrapotassium pyrophosphate and 10 wt% sodium ethyl hexyl sulfate is sprayed on with a hydraulic jet cleaner in the ratio 1 : 10 with water under pressure, so that 90 – 99 % of the adherent 3,3′-dichlorobenzidine is removed [32].

Wastes, such as production residues, contaminated disposable protective equipment, and empty packaging, which may contain diphenyl bases, are best incinerated. Suitable incinerators must have a secondary incineration compartment in which a dwell time of at least 0.3 s and a minimum temperature of 900 °C are maintained [33].

6. Characteristics of the Diphenyl Bases

6.1. Benzidines

Benzidine [*92-87-5*], 4,4′-biphenyl-diyldiamine, $C_{12}H_{12}N_2$, M_r 184.24, *mp* (coarse rods) 128 °C, crystallizes out of the melt usually in a metastable modification with a melting point of 122 – 125 °C, *bp* 400 – 401 °C at 98.7 kPa.

Benzidine crystallizes out of water above 80 °C in the anhydrous form; below 60 °C, it retains one molecule of water of crystallization; the monohydrate melts at 104 – 105 °C. Pure benzidine is colorless. One part by weight of benzidine dissolves in 2447 parts of water at 12 °C, in 106.5 parts of water at 100 °C, and in 45 parts of ether or 13 parts of absolute ethyl alcohol at 20 °C. Benzidine is diacidic; at 30 °C, $K_1 = 9.3 \times 10^{-10}$ and $K_2 = 5.6 \times 10^{-11}$. The heat of neutralization is 106.5 kJ/mol.

Benzidine slowly becomes discolored on exposure to air. It is chemically resistant to water. Blue, green, or red colorations and precipitates, many of which are based on quinonoid structures, form depending on the nature of the oxidizing agent and the reaction conditions used. These color reactions can be used to detect numerous oxidizing agents.

When chlorine is passed into a suspension of benzidine hydrochloride in concentrated hydrochloric acid, 3,3′,5,5′-tetrachlorobenzidine [*41687-08-5*] is formed. Bromine forms the corresponding tetrabromobenzidine [*62477-23-0*]. 2-Nitrobenzidine [*2243-78-9*], 2,2′-dinitrobenzidine, and a little 2,3′-dinitrobenzene are formed from benzidine sulfate in concentrated sulfuric acid upon the addition of potassium nitrate [34]. Sulfonic acids or sulfones of benzidine are formed under sulfonating conditions. The N-acetylation products, which also occur as metabolites in animal digestion, are formed with acetic anhydride. They are *N*-acetyl-benzidine [*3366–61-8*], $C_{14}H_{14}N_2O$, and *N,N′*-diacetylbenzidine [*613–35–4*], $C_{16}H_{16}N_2O_2$.

The most important commercial reaction is the diazotization of the two amino groups. Reaction with nitrous acid converts benzidine into the tetrazonium compound [13], in which the first diazonium group is coupled very vigorously whereas the second reacts more slowly. As a result it is possible to produce asymmetrical diazo dyes. Gradual diazotization is also possible (→ Azo Dyes).

In the presence of acids, benzidine forms salts that are difficult to dissolve. Among these are benzidine monohydrochloride [*14414–68–7*], $C_{12}H_{12}N_2 \cdot HCl$, needles, sparingly soluble in water, readily soluble in dilute hydrochloric acid; benzidine dihydrochloride [*531-85-1*], $C_{12}H_{12}N_2 \cdot 2\,HCl$, flakes, readily soluble in water and in alcohol. The dihydrochloride hydrolyzes to form the monohydrochloride and hydrochloric acid.

Benzidine sulfate [*531-86-2*], $C_{12}H_{12}N_2 \cdot H_2SO_4$, forms microscopic flakes and is virtually insoluble in water and alcohol. Because of its poor solubility, benzidine sulfate can be used for the quantitative determination of sulfuric acid. Benzidine disulfate, $C_{12}H_{12}N_2 \cdot 2\,H_2SO_4$, is formed from benzidine sulfate and sulfuric acid.

Benzidine has been produced from nitrobenzene on an industrial scale since about 1880. Commercial production methods include alkaline iron reduction [14], amalgam reduction, and electrochemical reduction. The resultant hydrazobenzene is rearranged with hydrochloric acid or sulfuric acid during cooling. The base is then isolated in the form of benzidine hydrochloride or benzidine sulfate. The conversion of these salts to the free base is avoided as much as possible because of the chronic toxicity of benzidine.

An aqueous benzidine solution gives a blue coloration in the presence of aqueous potassium ferricyanide. The sensitivity is about 10 mg/kg.

In very dilute colorless bromine water, benzidine yields a blue coloration. The solution turns green when more reagent is added and finally becomes colorless again upon the precipitation of reddish flakes. Quantitative determination is by titration with 0.1 N sodium nitrite solution in hydrochloric acid, using potassium iodide and starch paper as the indicator. Quantitative determination of benzidine in dyestuffs involves petroleum ether extraction, column chromatographic separation, and colorimetric determination [35]. Benzidine can be detected in urine or air by extraction with *m*-cresol methyl ether and reaction with potassium 1,2-naphthoquinone-4-sulfonate [*5908-27-0*]; the detection limit is 0.33 mg/kg [36], [37]. A simple and rapid method for the detection of benzidine in the urine is based on its the color-forming reaction with cyanogen bromide; the detection limit is 0.05 mg/kg [38]. Benzidine in the urine can be separated from its metabolites by means of paper chromatography [39].

Benzidine is used as the reagent base for the production of a large number of dyes, particularly azo dyes for wool, cotton, and leather. However, because benzidine has been found to be car-

cinogenic in humans, there has been a marked decline in the use of the benzidine dyes.

Benzidine is used for the quantitative determination of sulfuric acid and for the detection and determination of numerous anions and metal ions. The reaction of benzidine with pyridine in the presence of elemental chlorine is suitable for detecting traces of free chlorine or pyridine in drinking water [38]. The green to blue coloration which occurs when benzidine reacts with hydrogen peroxide in the presence of peroxidases can be used to detect blood [40]. Benzidine still plays a role in many chemical syntheses.

3,3′,4,4′-Tetraaminodiphenyl [*91-95-2*], diphenyl tetramine, 3,3′,4,4′-biphenyltetrayltetramine, $C_{12}H_{14}N_4$, M_r 214.27, *mp* 178 °C, forms fused blocks and flakes which turn a dark color upon exposure to air; it is soluble in hot water.

The hydrochloride [*7411-49-6*], $C_{12}H_{14}N_4 \cdot 4\,HCl \cdot 2\,H_2O$, forms needles and is readily soluble in water. The sulfate, $C_{12}H_{14}N_4 \cdot H_2SO_4$, forms small needles, is sparingly soluble in cold water, alcohol, and ether, and is soluble in hot water.

3,3′,4,4′-Tetraaminodiphenyl can be produced from benzidine by acetylation followed by nitration, saponification, and reduction with iron powder and hydrochloric acid [41].

The reduction of 3,3′-dinitrobenzidine can be carried out with hydrogen using a catalyst [42], with sodium dithionite in aqueous methanol, or (for preparative purposes) with tin(II) chloride and hydrochloric acid. The reaction of 3,3′- dichlorobenzidine with ammonia at high temperature and under pressure can also be used [43]. The crude product can be purified by recrystallization from aqueous sulfuric acid [44].

3,3′,4,4′-Tetraaminodiphenyl is suitable for the production of fibers based on polybenzimidazole. These fibers are resistant to high temperature and to chemicals. Fabrics made from them do not burn, do not melt in contact with a flame, and do not become hard when carbonized. They are suitable for the production of protective clothing and flue–gas filters and as substitutes for asbestos [45].

6.2. Tolidines

***o*-Tolidine** [*119-93-7*], 3,3′-dimethyl-4,4′-biphenyl-diyldiamine, $C_{14}H_{16}N_2$, M_r 212.30, *mp* 130 °C, colorless (in technical grades also brownish flakes), sparingly soluble in water, readily soluble in alcohol and ether. *o*-Tolidine is diacidic; at 30 °C, $K_1 = 6.2 \times 10^{-10}$, and $K_2 = 2.9 \times 10^{-10}$.

o-Tolidine barely becomes discolored upon exposure to air. It is chemically resistant to water. Numerous color reactions occur as a result of oxidation, e.g., an intense blue coloration forms on exposure to bromine or chlorine vapors. As with benzidine, these color reactions form the basis of a number of methods of detection and determination, such as those used for chlorine in air or water, for nitrates, and for hydrogen peroxide.

Mono- and disulfonic acids and *o*-tolidine-6,6-sulfone can be formed from *o*-tolidine sulfate.

o-Tolidine forms acid salts, such as *o*-tolidine hydrochloride, $C_{14}H_{16}N_2 \cdot HCl$, flakes. At 12 °C, one part dissolves in 112.4 parts of water.*o*-Tolidine dihydrochloride [*612-82-8*], $C_{14}H_{16}N_2 \cdot 2\,HCl$, forms crystals. At 12 °C, one part dissolves in 17.3 parts of water. *o*-Tolidine sulfate, $C_{14}H_{16}N_2 \cdot H_2SO_4$, forms needles or flakes. Water at 20 °C dissolves 0.12 g per 100 mL and more in the presence of hydrochloric acid. *o*-Tolidine disulfate [*64969-36-41*], $C_{14}H_{16}N_2 \cdot 2\,H_2SO_4$ forms crystals and is sparingly soluble in water.

o-Nitrotoluene undergoes alkaline reduction with zinc dust [13], electrolytic reduction [46], and catalytic reduction to form 2,2′-dimethylhydrazobenzene. This is rearranged using dilute hydrochloric acid or 20 % sulfuric acid at 5 – 50 °C. The free base or the dihydrochloride can be isolated.

The color reactions previously described can also be used for the detection of *o*-tolidine. Quantitatively, it is determined by titration with nitrite, as was described for benzidine.

o-Tolidine can be detected in the urine by extraction with 2,4-dichloroisopropylbenzene and conversion with potassium 1,2-naphthoquinone-4-sulfonate [47]. A rapid and simple procedure is based on the color reaction with cyanogen bromide; the detection limit in both cases is 0.05 mg/kg [38].

o-Tolidine is marketed as the free base and as the dihydrochloride. Both are supplied as moist products with a water content of 10–30 %.

o-Tolidine is a starting material in the production of a large number of azo dyes and pigments. *o*-Tolidine is used in the determination of oxygen and chlorine present in water, and for the colorimetric determination of cations of gold, cerium, and manganese.

An important derivative of *o*-tolidine is its diacetoacetyl compound, 4,4′-bisacetoacetylamino-3,3′-dimethyl diphenyl, which is marketed under the trade name Naphtol AS-G. It is a coupling agent which is frequently used and in combination with chloroanilines gives yellow shades. *o*-Tolidinediisocyanate is employed as a cross-linking agent to make polymers.

***m*-Tolidine** [*84-67-3*], 2,2′-dimethyl-4,4′-bi-phenyl-diyl-diamine, $C_{14}H_{16}N_2$, M_r 212.30, *mp* 109 °C, forms prisms from water, soluble in cold water, alcohol, and ether.

m-Tolidine gives no color in the presence of iron(III) chloride. It is tetrazotized with nitrite and acid and couples to form dyes.

m-Tolidine sulfate, $C_{14}H_{16}N_2 \cdot H_2SO_4$, is insoluble in cold alcohol, sparingly soluble in cold water, and soluble in hot water.

m-Tolidine is made by the reduction of *m*-nitrotoluene with zinc dust and sodium hydroxide solution [13]. The subsequent rearrangement is carried out with hydrochloric acid or sulfuric acid and gives rise to *m*-tolidine dihydrochloride or *m*-tolidine sulfate, which are isolated as salts. The free base is difficult to isolate and is therefore not a commercial product.

m-Tolidine was used in the past for the production of azo dyes.

6.3. Halogenated Benzidines

2,2′-Dichlorobenzidine [*84-68-4*], 2, 2′-dichloro-4, 4′-biphenyl-diyldiamine, $C_{12}H_{10}Cl_2N_2$, M_r 253.13, *mp* 166.8 °C, forms prisms from alcohol. It is almost insoluble in water but readily soluble in alcohol.

2,2′-Dichlorobenzidine dihydrochloride, $C_{12}H_{10}Cl_2N_2 \cdot 2\,HCl$, crystallizes in the form of flakes from water and is relatively soluble in water.

2,2′-Dichlorobenzidine is made from *m*-nitrochlorobenzene, preferably using zinc dust and sodium hydroxide solution. It is subsequently rearranged and isolated in the form of a dihydrochloride.

3,3′-Dichlorobenzidine [*91-94-1*], 3,3′-dichloro-4,4′-biphenyl-diyldiamine, $C_{12}H_{10}Cl_2N_2$, M_r 253.13, *mp* 132 – 133 °C, forms needles from alcohol or benzene. The commercial product is light brown to violet in color. It is virtually insoluble in water but readily soluble in alcohol, benzene, and glacial acetic acid.

3,3′-Dichlorobenzidine is barely discolored on exposure to air and is chemically resistant to water. Oxidizing agents, such as bromine water, potassium dichromate, and iron(III) chloride, cause the formation of a green color. With gold, the green color is still detectable at a dilution of 1 : 5000000.

N-Acetyl-3,3′-dichlorobenzidine and *N,N*′-diacetyl-3,3′-dichlorobenzidine form when 3,3′- dichlorobenzidine is treated with acetic anhydride in dilute alcohol. The tetrazotizing behavior is similar to that of benzidine and *o*-tolidine.

3,3′-Dichlorobenzidine dihydrochloride [*612-83-9*], $C_{12}H_{10}Cl_2N_2 \cdot 2\,HCl$, is sparingly soluble in water and readily soluble in alcohol. It is marketed in the form of a colorless to pale grey crystalline powder.

3,3′-Dichlorobenzidine is made from *o*-nitrochlorobenzene by reduction with zinc dust and sodium hydroxide solution and subsequent rearrangement with dilute hydrochloric acid or sulfuric acid. It is assayed by titration with sodium nitrite solution in dilute hydrochloric acid and detected in human urine by colorimetry using chloramine. The detection limit is 0.1 mg/kg [38].

Like *o*-tolidine, 3,3′-dichlorobenzidine is marketed as a free base and as the dihydrochloride. Both are supplied as moist products with water contents of 5 – 30 %. The so-called *urethane quality* is taken to mean an anhydrous base, free of hydrochloric acid.

3,3′-Dichlorobenzidine was introduced about 1932 and is now the most important diphenyl base. It is used as the starting material for pigments with yellow and red shades. These are used for coloring printing inks, paints, plastics, and rubbers. The important diarylide yellow pigments, which are incorrectly known as benzidine yellows, are formed by the combination of 3,3′-dichlorobenzidine with acetic acid arylides. 3,3′-Dichlorobenzidine is also used in the production of polyurethane rubbers.

2,2′,5,5′-Tetrachlorobenzidine [*15721-02-5*], 2,2′,5,5′-tetrachloro-4,4′-biphenyldiyldiamine, $C_{12}H_8Cl_4N_2$, M_r 322.02, *mp* 134 – 137 °C.

2,2′,5,5′-Tetrachlorobenzidine is made by the reduction of 2,5-dichloronitrobenzene with zinc dust and sodium hydroxide solution. The subsequent rearrangement is carried out using sulfuric acid or hydrochloric acid. The dihydrochloride melts at 230 °C. Tetrachlorobenzidine is marketed as the free base and is used to produce yellow pigments.

6.4. Alkoxybenzidines

***o*-Dianisidine** [*119-90-4*], 3,3′-dimethoxy-4,4′- biphenyl-diyldiamine, $C_{14}H_{16}N_2O_2$, M_r 244.30, crystallizes dimorphically, rarely in needles, with *mp* 133 °C, often in flakes with *mp* 137 – 138 °C. It forms colorless crystals, but commercial products have a tinge of violet. It is sparingly soluble in water but soluble in alcohol, ether, and benzene. One gram of ethyl acetate dissolves 0.285 g of *o*-dianisidine at 73 °C.

The pure compound is stable upon exposure to air, but commercial products turn violet. *o*-Dianisidine is resistant to water but sensitive to oxidizing agents.

o-Dianisidine dihydrochloride [*20325-40-0*], $C_{14}H_{16}N_2O_2 \cdot 2\,HCl$, forms prisms with *mp* 272 °C (decomp.). It is readily soluble in hot water and sparingly soluble in cold water and alcohol.

The hydrazo compound (2,2′-dimethoxyhydrazobenzene [*787-77-9*]) is obtained by the reduction of *o*-nitroanisole [*91-23-6*] with zinc dust and sodium hydroxide solution, often in a medium containing ethyl alcohol.

The reduction can also be performed electrochemically or with a palladium catalyst in an aqueous solution of isopropyl alcohol and sodium hydroxide. Rearrangement is carried out at a maximum of 20 °C with 20 % sulfuric acid [13], [14].

Like benzidine and *o*-tolidine, *o*-dianisidine forms colors with numerous oxidizing agents, e.g., copper, cobalt, and gold ions. *o*-Dianisidine is quantitatively determined by titration with nitrite using potassium iodide and starch paper as the indicator. *o*-Dianisidine can be detected in the urine using potassium 1,2-naphthoquinone-4-sulfonate after extraction [47]. A rapid and easy method is based on the color formed with cyanogen bromide. Its detection limit is 0.05 mg/kg [38].

The free *o*-dianisidine base and the dihydrochloride are marketed in moist forms with a 10 – 30 % water content.

o-Dianisidine is a starting material for the production of disazo dyes and pigments.

***o*-Diphenetidine** [*6264-77-3*], 3, 3′-diethoxy- 4, 4′-biphenyl-diyldiamine, $C_{16}H_{20}N_2O_2$, M_r 272.35, *mp* 119 °C, forms needles or flakes. It assumes a grey or violet shade in commercial products. It is insoluble in cold water, slightly

soluble in boiling water, and very soluble in alcohol, ether, and chloroform.

The aqueous solution turns red on contact with oxidizing agents, such as bromine, iron(III) chloride, or potassium permanganate. The dihydrochloride melts at 254 °C with decomposition.

o-Diphenetidine is made from 2-nitro-1-ethoxybenzene [*610-67-3*] by reduction using zinc dust, followed by rearrangement using hydrogen chloride gas in ethanol or dilute sulfuric acid.

Dichlorodianisidine [*5855-70-9*], 2,2′-dichloro-5,5′-dimethoxy-4,4′-biphenyl-diyldiamine, $C_{14}H_{14}Cl_2N_2O_2$, M_r 313.19, *mp* 175 °C, is a violet crystalline powder.

Dichlorodianisidine is made from 4-chloro-2-nitro-1-methoxybenzene [*89-21-4*] by zinc dust reduction. Dichlorodianisidine is used in special pigments.

6.5. Benzidinecarboxylic Acids

Benzidine-2,2′-dicarboxylic acid [*17557-76-5*], 4,4′-diaminobiphenyl-2,2′-dicarboxylic acid, $C_{14}H_{12}N_2O_4$, M_r 272.26, *mp* 265 °C, crystallizes from water in needles. It is sparingly soluble in water, alcohol, and ether. The dihydrochloride, $C_{14}H_{12}N_2O_4 \cdot 2\,HCl$, crystallizes in columns or needles.

Benzidine-2,2′-dicarboxylic acid is made from 3-nitrobenzoic acid [*121-92-6*] by reduction with zinc dust and sodium hydroxide solution to form the hydrazo compound. This is followed by rearrangement using hydrochloric acid to form the dihydrochloride.

Benzidine-3,3′-dicarboxylic acid [*2130-56-5*], 4,4′-diaminobiphenyl-3,3′-dicarboxylic acid, $C_{14}H_{12}N_2O_4$, M_r 272.26, crystallizes into needles which are converted into benzidine by decarboxylation at temperatures above 250 °C. It is slightly soluble in alcohol and ether.

Benzidine-3,3′-dicarboxylic acid is made by reducing 2-nitrobenzoic acid [*552-16-9*] with zinc dust and sodium hydroxide solution. The resultant hydrazobenzene-2,2′-dicarboxylic acid [*612-44-2*] is rearranged by heating with hydrochloric acid. The free benzidine-3,3′-dicarboxylic acid is precipitated from the hydrochloric acid solution by adding ammonia or sodium acetate [13]. Electrolytic reduction followed by rearrangement with dilute sulfuric acid is also possible.

Benzidine-3,3′-dicarboxylic acid is used for the manufacture of azo dyes containing copper.

6.6. Benzidinesulfonic Acids and Benzidinesulfones

Benzidine-2,2′-disulfonic acid [*117-61-3*], 4,4′-diaminobiphenyl-2,2′-disulfonic acid, $C_{12}H_{12}N_2O_6S_2$, M_r 344.37, crystallizes in monoclinic prisms, chars without melting. One hundred grams of the aqueous solution at 22 °C contains 0.0791 g of the anhydrous acid. The compound is virtually insoluble in alcohol and ether.

Benzidine-2,2′-disulfonic acid is made from the potassium or sodium salt of 3-nitrobenzenesulfonic acid by a gradual reduction using zinc dust and sodium hydroxide solution in a dilute aqueous solution. The product is subsequently rearranged using hydrochloric acid or dilute sulfuric acid [13]. Electrochemical or catalytic reductions are also possible [48].

The sulfonic acid must be diazotized indirectly because of its poor solubility. This is achieved by dissolving it in the necessary amount of sodium hydroxide solution, mixing the neutral solution with sodium nitrite and allowing the mixture to trickle into hydrochloric or sulfuric acid in a thin stream [13].

Benzidine-2,2′-disulfonic acid is used in the production of yellow and red azo dyes.

Benzidine-3,3′-disulfonic acid [*3365-90-0*], 4,4′-diaminobiphenyl-3,3′-disulfonic acid, $C_{12}H_{12}N_2O_6S_2$, M_r 344.37, forms tetrahedral flakes, virtually insoluble in alcohol and ether, very slightly soluble in boiling water.

Benzidine-3,3′-disulfonic acid is made by reacting one part of benzidine sulfate with two parts of sulfuric acid monohydrate at 210 °C.

***o*-Tolidine-6,6′-disulfonic acid** [*83-83-0*], 4,4′-diamino-5,5′-dimethylbiphenyl-2,2′-disulfonic acid, $C_{14}H_{16}N_2O_6S_2$, M_r 372.42, crystallizes from water in needles. One hundred grams of the aqueous solution at 18 °C contains 0.226 g of the anhydrous acid. The substance is insoluble in alcohol, ether, and glacial acetic acid.

o-Tolidine-6,6′-disulfonic acid is produced from 2-nitrotoluene-4-sulfonic acid [*97-06-3*] by reduction with zinc and sodium hydroxide solution and subsequent rearrangement.

o-Tolidine-6,6′-disulfonic acid is used to make yellow dyes for wool.

Benzidinesulfone [*6259-19-4*], 3,7-diaminodibenzothiophene-5,5-dioxide, $C_{12}H_{10}N_2O_2S$, M_r 246.29, forms yellow needles or flakes, *mp* 330 – 332 °C, is virtually insoluble in boiling water, boiling alcohol, ether, and benzene.

The dihydrochloride, $C_{12}H_{10}N_2O_2S \cdot 2\,HCl$, crystallizes as flakes from dilute hydrochloric acid and is decomposed by water. The sulfate, $C_{12}H_{10}N_2O_2S \cdot H_2SO_4 \cdot 1.5\,H_2O$, crystallizes as needles or flakes, is slightly soluble in water containing sulfuric acid, and is decomposed by water.

Benzidinesulfone is produced by heating benzidine sulfate with an excess of 20 – 40 % oleum in a water bath.

Benzidinesulfone-disulfonic Acid, 3,7-diaminodibenzothiophene-2,8-disulfonic acid 5,5- dioxide, $C_{12}H_{10}N_2O_8S_3$, M_r 406.41, crystallizes in pale yellow needles, soluble in hot water, slightly soluble in alcohol, virtually insoluble in cold hydrochloric acid and in dilute sulfuric acid.

Benzidinesulfone-disulfonic acid is made by heating benzidine or benzidine sulfate with 40 % oleum at 150 °C.

7. Economic Aspects

Because of the carcinogenic properties of benzidine, a number of older benzidine plants have been replaced by new ones built to meet the industrial hygiene requirements. At the same time, every effort is being made to replace benzidine with less dangerous bases. Thus the demand for benzidine, which once amounted to several thousand tons per year, has been falling for some time.

There are no statistics available on the world production of diphenyl bases, but in 1983 about 15 kt was produced. Dichlorobenzidine and its salts accounted for about 7 – 10 kt, followed by *o*-tolidine with 2 – 3 kt. In contrast, *o*-dianisidine production was only about 1 – 2 kt and the production of tetrachlorobenzidine hardly more than 100 t.

8. Toxicology

8.1. Benzidine

The *acute* oral LD_{50} of benzidine administered to male rats is 1.57 g/kg [49]. *Subacute* dietary exposure of mice to concentrations of

100 – 800 ppm resulted in cloudy swelling of the liver, vacuolar degeneration of the renal tubules, and hyperplasia of myeloid elements of the bone marrow and lymphoid cells in the thymus and spleen [50]. Little is known about the *dermal* or *pulmonary absorption,* but the toxic systemic manifestations following these modes of exposure indicate that proportional amounts are absorbed [51].

If benzidine is injected intravenously, its half-life in blood exhibits several phases. The fourth and final phase has a half-life of 65 h in rats and 88 h in dogs [52]. The routes of elimination differed in the various animal species investigated. In rats, approximately 80 % of an i.v. dose was excreted via feces. In dogs and monkeys 67 % and in monkeys 50 % was eliminated via the urine [52].

Benzidine is metabolized to *N*-acetylbenzidine and *N,N′*-diacetylbenzidine, which is converted by an NADPH-dependent reaction to *N*-hydroxy-*N,N′*-diacetylbenzidine and 3-hydroxy-*N,N′*-diacetylbenzidine; the latter binds to nucleic acids [53].

Benzidine is positive in the Ames test following metabolic activation with liver homogenate from rats [54], [55] or humans [56]. The Ames test is also positive for the urine of rats that have been exposed to benzidine by oral administration [57]. *N*-Acetylbenzidine [57] and *N*-hydroxy-*N,N′*-diacetylbenzidine [53] also induce point mutations in the Ames system. Benzidine induces unscheduled DNA synthesis in HeLa cells [58] and in rat hepatocytes [59]. After metabolic activation, DNA strand breaks [60], [61] and cell transformation [62], [63] occur in V-79 cells.

Benzidine hydrochloride produces hepatocellular carcinoma in mice at a dose level of 150 mg/kg [64–67]. Evidence of the carcinogenic properties of benzidine has been found in rats [68] and hamsters [69].

The first information about the carcinogenic properties of benzidine in humans was published by Oppenheimer in 1927 [70]. He observed tumors of the bladder among workers in the dyestuffs industry. This observation has been confirmed by many other researchers [71–80]. The incidence of bladder cancer in workers decreased after reduction of the industrial exposure [80].

In summary, there is sufficient evidence that benzidine is carcinogenic in mice, rats, and hamsters. Ample evidence exists that benzidine also is carcinogenic in humans.

The MAK commission has classified benzidine in group A 1 (clearly carcinogenic). The American Conference of Governmental Industrial Hygienists (ACGIH) lists benzidine in group A 1 b: "no exposure or contact by any route – respiratory, skin, or oral, as detected by the most sensitive methods – shall be permitted."

8.2. 3,3′-Dichlorobenzidine

The oral LD_{50} (rat) of 3,3′-dichlorobenzidine is 7.07 g/kg [81].

In chronic studies 100 mg was administered orally to beagle dogs three times weekly for six weeks and five times weekly thereafter for seven years. Serum-glutamic-oxalacetic transaminase levels were increased [82], a sign of a slightly toxic effect upon the liver. Carcinoma of the bladder, hepatocellular carcinoma, and mammary gland tumors were also observed.

3,3′-Dichlorobenzidine is rapidly metabolized. After an oral dose of one gram, dogs excrete only 2 % unchanged in the feces and urine [83]. Rats and dogs treated with 3,3′-dichlorobenzidine showed multiphasic blood clearances. The half-life of the final phase was 68 h in rats and 86 h in dogs. The majority of the administered dose was recovered from the bile, thereby demonstrating the importance of the hepato-biliary excretion [52].

In the Ames test, 3,3′-dichlorobenzidine was positive with and without adding a metabolic activation system [55], [84], [85]. Positive results were also obtained in the unscheduled DNA synthesis test in HeLa cells [58] and in the cell transformation assay in baby hamster kidney cells [86].

When mice were treated with 3,3′-dichlorobenzidine in a dietary concentration of 1000 ppm for one year, all of the animals developed hepatomas [87]. In another experiment, rats developed tumors in various organs after an exposure for one year followed by an unlimited observation period [88]. The results are difficult to evaluate because of the absence of an adequate control group. When rats were treated with 1000 ppm of 3,3′-dichlorobenzidine in the

diet, significant statistical increases were found for granulocytic leukemias, mammary adenocarcinomas, and zymbal gland carcinomas [89]. Hamsters did not develop tumors at the same dose level, but following doses of 3000 ppm, tumors of the bladder and the liver were observed [69], [90].

In epidemiological studies of workers exposed to 3,3′-dichlorobenzidine, no bladder tumors were found [81], [91], [92]. In summary, 3,3′-dichlorobenzidine is carcinogenic in laboratory animals, but proof of its oncogenic properties in humans does not exist. Both commissions (MAK and ACGIH) have classified this compound in category 2, respectively, group A II. Neither MAK nor TLV values have been established. 3,3′-Dichlorobenzidine is absorbed by the skin.

8.3. *o*-Tolidine (3,3′-Dimethylbenzidine)

o-Tolidine can enter the body by percutaneous absorption, ingestion, or inhalation [93]. It is metabolized in exposed workers to diacetyl-*o*-tolidine and to a hydroxyamino metabolite (probably 5-hydroxy-*o*-tolidine), which are excreted via the urine [94]. Dogs are unable to acetylate aromatic amines such as *o*-tolidine [95].

In the Ames test, *o*-tolidine is a weak mutagen [85], [96]. *o*-Tolidine acts as a systemic carcinogen in Sherman rats when administered subcutaneously at a dose level of 60 mg per rat per week. It induces mainly tumors of the zymbal glands [97]. No carcinogenic potential could be observed in hamsters after feeding them a diet containing 1000 ppm of *o*-tolidine [69], [90]. No epidemiological studies in humans are available.

Exposure limits have been established. The MAK value is 5 mg/kg (22 mg/m^3, group III B), and the TLV is 2 mg/kg (9 mg/m^3, group A 2).

8.4. *o*-Dianisidine (3,3′-Dimethoxybenzidine)

Information about the biotransformation of *o*-dianisidine is rather limited. In dogs, 3,3′- dihydroxybenzidine is formed as a major metabolite [83].

In the presence of rat liver homogenate, *o*-dianisidine is positive in the Ames test [85]. It is capable of inducing unscheduled DNA synthesis in HeLa cells [58] and in primary rat hepatocytes [98], and it provokes cell transformation in baby hamster kidney cells in vitro [86]. *o*-Dianisidine is carcinogenic in rats. An oral dose of 30 mg administered three times per week for 13 months produced tumors in the zymbal glands [98], [99] and in other tissues [100], [101].

No conclusive epidemiological studies have been reported on the carcinogenicity of *o*-dianisidine in humans. No MAK value has been established. *o*-Dianisidine is classified in group III B.

1. Introduction

Benzoic acid [*65-85-0*], $C_7H_6O_2$. The name benzoic acid originates from gum benzoin, a balsamic resin obtained from a South Asian plant called styrax. The extraction of benzoic acid was carried out by SCHEELE in 1775. Its structure was determined by LIEBIG and WÖHLER in 1832. The initial production methods were developed in the late 1800s. They were based on the hydrolysis of benzotrichloride or the decarboxylation of phthalic anhydride. Today, benzoic acid is produced by oxidation of toluene with air, which has displaced dichromate and nitric acid oxidation processes.

Occurrence. Benzoic acid and its derivatives are widely distributed in nature. Gum benzoin contains from 12 – 18 % benzoic acid in free and esterified forms. Other natural products containing benzoic acid are the bark, foliage, fruits, and seeds of various plants, including cherries and prunes. Hippuric acid, found in the urine of herbivores, is a glycine derivative of benzoic acid.

2. Physical Properties

Benzoic acid, benzenecarboxlic acid, M_r 122.12, *mp* 122 °C, *bp* 250 °C, forms white monoclinic crystals that begin to sublime at about 100 °C. It is volatile in steam and forms azeotropes with biphenyl, butyl benzoate, catechol, diphenyl ether, diphenylmethane, and naphthalene. At 89.7 °C, a mixture of excess benzoic acid and water forms two stable liquid phases. The water content of the benzoic acid phase is 26.5 wt %. The two phases become homogeneous at 117.2 °C. The mixture then contains 32.34 % benzoic acid and 67.66 % water.

Some physical properties of benzoic acid are listed in the following:

Solubility in water, g/100 g	
at 0 °C	0.17
at 20 °C	0.29
at 40 °C	0.60
at 60 °C	1.20
at 80 °C	2.75
at 95 °C	6.85
Solubility in organic solvents at 25 °C, g/100 g	
Acetone	55.60
Benzene	12.17
Tetrachloromethane	4.14
Ethanol (absolute)	58.40

3. Chemical Properties

Benzoic acid is stable towards common oxidizing agents. Air, permanganate, chromic acid, hypochlorite, and dilute nitric acid do not affect it. However, above 220 °C it reacts with copper(II) salts to form phenol and its derivatives [1]. This reaction, followed by regeneration of the copper(II) with molecular oxygen, is the basis for the commercial production of phenol from benzoic acid [2] (→ Phenol). Benzoic acid reacts with ammonia under similar conditions to form aniline [3]. Upon heating to 150 °C, some dehydration takes place to form benzoic anhydride. Decarboxylation occurs when benzoic acid is heated above 370 °C or as low as 245 °C in the presence of catalysts [4]. Benzene and a small amount of phenol are formed. Copper and cadmium powder accelerate the decarboxylation. When potassium benzoate is heated in carbon dioxide, it disproportionates to terephthalate and benzene. Cadmium and zinc salts catalyze this reaction. Benzoic acid is converted into hydroxybenzoic acids by fused potassium hydroxide [5].

Benzoic acid can be directly hydrogenated with molecular hydrogen to afford benzaldehyde in quantitative yield. Zirconium and other metal oxides catalyze the reaction [31]. Hydrogenation on noble metal catalysts gives cyclohexanecarboxylic acid (hexahydrobenzoic acid). Chlorination yields chiefly 3-chlorobenzoic acid [6]. Nitration forms 3-nitrobenzoic acid [7], and sulfonation forms 3-sulfobenzoic acid.

4. Production

Liquid-Phase Oxidation of Toluene with Molecular Oxygen. This process was developed by I.G. Farbenindustrie in Germany during World War II and was operated until the end of the war [8]. The plant consisted of a bubble-column oxidation reactor made of aluminum-lined steel and equipped with an air inlet tube, a separator, and an absorber to recover toluene. The reactor contained heat-exchange coils to remove the great amount of heat generated in the reaction. The purity of the toluene was critical because sulfur compounds, nitrogen compounds, phenols, and olefins inhibit the oxidation reaction. The reaction was carried out at 140 °C and ca. 0.2 MPa with a cobalt naphthenate catalyst (0.1 %) for 30 h. About 50 % conversion of toluene was achieved, 80 % of which formed benzoic acid. Other oil-soluble cobalt salts were also used as catalysts. The crude oxidation product was neutralized with sodium carbonate to produce sodium benzoate. Unreacted toluene was recovered from the spent oil phase by distillation.

The elemental mechanism of this oxidation is a free-radical chain process [9]. The cobalt catalyst shortens the induction period of the reaction and retards the accumulation of inhibitors. Peroxides are reaction intermediates. Manganese behaves similarly to cobalt as a catalyst, but its performance is weaker. Copper adversely affects the oxidation. High pressures retard the reaction, especially at lower catalyst concentrations. Above 130 °C, the reaction rate is determined by the diffusion of oxygen. Phenolic compounds gradually accumulate during the reaction and eventually inhibit it.

In a typical modern process the oxidation is conducted at 165 °C and 0.9 MPa. The reaction heat is removed by external circulation of the contents of the reactor. The pressure of the liquid discharged form the reactor is reduced to atmospheric, and unreacted toluene is recovered. Benzoic acid is purified by rectification. The bottom residue is extracted to recover the cobalt

catalyst. The exhaust gas is cooled to recover most of the toluene, purified, and vented. The oxidation reactor can be a bubble column or a stirred tank. Stainless steel is generally used as the construction material. Heat removal is still a serious problem, and air distribution within the reactor is critical to prevent a runaway reaction. The oxygen content of the exhaust gas should be strictly monitored to avoid an explosion.

The oxidation produces several byproducts. Benzaldehyde is formed in fairly large amounts, especially at lower conversions. It can be recovered by distillation. A limited amount of benzyl alcohol is formed, but its recovery is impractical because of the unavoidable esterification with benzoic acid. Benzyl benzoate can be recovered from the bottoms of the benzoic acid column [10]. Other esters, including benzyl formate and benzyl acetate, are also present. Biphenyl and methylbiphenyls are formed in smaller amounts. Because their vapor pressures are close to that of benzoic acid, they play a role in the rectification of benzoic acid. The product is contaminated by small amounts of phthalic acid. Carbon monoxide and carbon dioxide are detected in the exhaust gas. The yield of benzoic acid is about 90 %, but it varies with toluene conversion. At lower conversions, the selectivity for benzaldehyde and benzyl alcohol exceeds 10 %.

Conventional technical-grade benzoic acid is usually of as-rectified quality. Further processing is necessary for higher grade products. Sublimation, recrystallization, and neutralization processes have been proposed. Thermal treatment in an inert atmosphere is attempted [11]. To remove phthalic acid, whose presence is not allowed for food or pharmaceutical uses, treatment with amines [32] and rinsing [33] methods have been reported. Methylbiphenyls are responsible for the odor of the product. For their removal, extraction [34] and treatment in an inert gas stream [35] have been proposed.

The oxidation reactions of alkylaromatic hydrocarbons are dramatically enhanced by adding bromine compounds to the cobalt catalyst in acetic acid [12]. This method is now widely used in the production of terephthalic acid and is also applicable to the benzoic acid process. Under certain conditions, benzoic acid itself can be used as a solvent. Manganese has synergistic effect on the cobalt catalyst. This process can realize high reaction rates and better toluene conversion, as well as eliminating reaction inhibition. However, to avoid corrosion, the equipment must be constructed of expensive titanium.

Another type of cobalt catalyst activator is a readily oxidizable carbonyl compound such as methyl ethyl ketone or acetaldehyde. These additives permit a considerable reduction in reaction temperature, but because of the high consumption of these activators, this technology does not seem to be practical.

The catalytic oxidation of toluene in aqueous sodium hydroxide directly affords sodium benzoate. This process has been tried since 1940s, but satisfactory yields have not been achieved.

Vapor-phase oxidation of toluene at higher temperatures is another potential process. Various catalysts (vanadium, tungsten, uranium, molybdenum, silver, etc.) have been investigated, but yields were not comparable to those of the liquid-phase process. However, a patent claims a significant improvement in yield by using complex vanadia catalysts [36].

5. Quality Specifications

Quality specifications for benzoic acid are listed in Tables 1 and 2. An EU guideline for the use of benzoic acid and its derivatives has been issued [37].

6. Storage, Transportation and Legal Aspects

Benzoic acid is commercially handled as flakes packed in 25 kg paper bags or in 500 kg flexible containers. Bulk quantities are transported as molten liquid in stainless steel vessels. For transport, benzoic acid is not regulated as a hazardous material (IMO, IATA, ADR/SDR, and RID/SDR). There is no IMDG code. The reportable quantity in USA is 2270 kg (40 CFR 355.40). The European hazard-labeling symbol is Xn (harmful). The MSDN is available on the Internet [38], [39].

Benzoic acid can be stored without deterioration, but the low-grade product tends to solidify on storage. Precautions should be taken against dust during handling since it irritates the

eyes and skin. Dust/air mixtures can be explosive above the flash point (121°C). The explosion limit of the vapor/air mixture is 0.085-0.99g/m^3.

Benzoic acid has the following registry number for the legal control: TSCA 65-85-0, EINECS (European Inventory of Existing Chemical substances) 200-618-2, ECNS (Japan) (3)-1397, RTECS DG0875000.

7. Uses and Economic Aspects

The majority of the benzoic acid is utilized captively to produce phenol. The rest comes onto the market. The benzoic acid market in the USA and Japan is summarized in Table 3. Major producers are listed in Table 4.

Glycol esters of benzoic acid are used as plasticizers for vinyl resins. Demand has increased in the USA as a replacement for butyl benzyl

phthalate in poly(vinyl acetate) emulsion adhesives [40]. Another major market is sodium benzoate for preservatives and anticorrosives. Benzoic acid is used in modified alkyd resins for automotive refinishing enamels to improve surface properties. Benzoic acid is also used as an intermediate for perfumes, pharmaceuticals, and cosmetics. The market in USA has experienced growth rate of 4 % per annum [42].

8. Derivatives of Benzoic Acid

8.1. Salts of Benzoic Acid

Sodium benzoate [*532-32-1*], $C_7H_5O_2Na$, M_r 144.11, forms white granules, flakes, or a crystalline powder with a sweetish taste. One gram dissolves in 2 mL of water. Between 0 °C and 50 °C the solubility in water is nearly constant, but at higher temperature it increases sharply. At −13.5 °C, the eutectic mixture with water consists of 44.9 g of the salt and 100 g of water. The aqueous solution is slightly alkaline (pH ca. 8). Sodium benzoate is soluble to the extent of 0.8 g in 100 mL of ethanol, 8.2 g in 100 mL of methanol, and over 20 g in 100 mL of ethylene glycol. Aqueous and alcoholic solutions of sodium benzoate passivate the surfaces of metals and alloys.

Dry sodium benzoate is electrically charged by friction and forms an explosive mixture when its dust is dispersed in air. It absorbs moisture from air to some extent. Upon heating in an inert atmosphere, sodium benzoate carbonizes and forms sodium carbonate. In the presence of air, it burns to give carbon dioxide and sodium carbonate. Sodium benzoate reacts with benzoyl chloride to form benzoic anhydride [*93-97-0*]. Other salts of benzoic acid can be prepared by metathesis reactions with the salts of particular cations. Sodium benzoate is produced by the neutralization of benzoic acid with sodium hydroxide. Direct oxidation of toluene in sodium hydroxide solution is not currently in use.

The principal use of sodium benzoate is an anticorrosive. The expansion of the motor industry has increased demand. It is added mainly to antifreeze coolants. It is also used as a preservative for foods and cosmetics. Specifications for food-grade sodium benzoate are listed in Table 5. The CFR GRAS level is 0.1 % max., and its use below pH 4.5 is recommended [41].

Potassium benzoate [*582-25-2*], $C_7H_5O_2K$, M_r 160.22. At 17.5 °C, a saturated aqueous solution contains 41.1 wt % of the salt. It has similar properties to the sodium salt. It is used in the food industries where the presence of sodium is undesirable.

8.2. Esters of Benzoic Acid

Methyl benzoate [*93-58-3*], $C_8H_8O_2$, M_r 136.15, *mp* −12.21 °C, *bp* 199.5 °C, colorless liquid with a pleasant odor, n_D^{20} 1.516, d_4^{15}

1.09334, solubility in water at 20 °C 0.15 wt %, miscible with common organic solvents, vapor pressure 0.133 kPa at 39 °C, 13.3 kPa at 130.8 °C, flash point 83 °C, ignition point 505 °C, heat of combustion 3950 kJ/mol. Methyl benzoate forms an azeotrope (20.8 wt % ester) with water, *bp* 99.08 °C. Stable against oxidation and easily saponified by strong base.

Methyl benzoate is prepared by reacting methanol with benzoic acid. It is used as a perfume and as an intermediate in the production of other benzoic esters.

***n*-Butyl benzoate** [*136-60-7*], $C_{11}H_{14}O_2$, M_r 178.23, *mp* −22.4 °C, *bp* 250.3 °C, d_4^{20} 1.0061, flash point 111 °C; autoignition temperature 440 ± 5 °C, heat of combustion 5828 kJ/mol. Butyl benzoate forms an azeotrope (6 wt % ester) with water, *bp* 99.8 °C. Butyl benzoate is widely used as a dye carrier in polyester fibers.

Glycol Benzoates. *Diethylene glycol dibenzoate* [*120-55-8*], $C_{18}H_{18}O_5$, M_r 314.34, *mp* −28 °C, *bp* 240 °C at 0.7 kPa, d_4^{20} 1.178, n_D^{25} 1.5424, flash point 232 °C.

Propylene glycol dibenzoate [*19224-26-1*], $C_{17}H_{16}O_4$, M_r 284.31, *fp* -3 °C, *bp* 232 °C at 1.6 kPa.

Dipropylene glycol dibenzoate [*27138-31-4*], $C_{20}H_{22}O_5$, M_r 342.40, *mp* −40 °C, *bp* 232 °C at 0.7 kPa, d_4^{20} 1.129, n_D^{25} 1.5282, flash point 212 °C.

Glycerine tribenzoate [*614-33-5*].

The glycol benzoates are used as plasticizers in poly(vinyl chloride), poly(vinyl acetate), and polacrylate resins.

Phenyl benzoate [*93-99-2*], $C_{13}H_{10}O_2$, M_r 198.21; monoclinic crystals, *mp* 70 °C; *bp* 314 °C, d_4^{20} 1.235, slightly soluble in water, soluble in hot ethanol. Phenyl benzoate is an intermediate in the production of phenol from benzoic acid.

Benzyl benzoate [*120-51-4*], $C_{14}H_{12}O_2$, M_r 212.25, leaflets or oily liquid, aromatic odor, *mp* 21 °C, *bp* 323 – 324 °C, *bp* 189 – 191 °C at 2.13 kPa, *bp* 156 °C at 0.6 kPa. It decomposes above 200 °C and is slightly volatile in steam and insoluble in water.

Benzyl benzoate is produced by esterifying dry sodium benzoate with benzyl chloride [13] or by the dimerization of benzaldehyde [14]. It is also obtained from the bottoms of benzoic acid rectification plants (see page 2).

Benzyl benzoate is used as a dye carrier. Other uses include solvents for cellulose derivatives, plasticizers, and fixatives in the perfume industry.

8.3. Benzoyl Chloride

Physical Properties. Benzoyl chloride [*98-88-4*], C_7H_5ClO, M_r 140.57, *mp* −0.6 °C, *bp* 198.3 °C, vapor pressure 0.133 kPa at 32.1 °C, 1.33 kPa at 73.8 °C, 13.3 kPa at 128 °C, colorless liquid with a penetrating odor, lachrymatory, fumes on exposure to air, n_D^{20} 1.55369, d_4^{20} 1.2113, decomposes in water and alcohols, miscible with benzene, flash point 102 °C, autoignition temperature 600 °C, heat of combustion 3282 kJ/mol.

Chemical Properties. Benzoyl chloride reacts violently with water to give benzoic acid and hydrochloric acid. If the amount of water is limited, benzoic anhydride is formed. Reaction with ammonia forms benzamide [*55-21-0*]. Benzoyl chloride is an excellent benzoylation reagent for compounds with active hydrogen, such as alcohols, phenols, or amines, under Friedel – Crafts and Schotten – Baumann reaction conditions.

Production. Benzoyl chloride is produced commercially from benzotrichloride [*98-07-7*], which is available by the chlorination of toluene. The chlorination reaction proceeds stepwise via benzyl chloride [*100-44-7*] and benzal chloride [*98-87-3*].

$$C_6H_5CH_3 + Cl_2 \longrightarrow C_6H_5CH_2Cl + HCl$$

$$C_6H_5CH_2Cl + Cl_2 \longrightarrow C_6H_5CHCl_2 + HCl$$

$$C_6H_5CHCl_2 + Cl_2 \longrightarrow C_6H_5CCl_3 + HCl$$

The benzotrichloride is then partially hydrolyzed with a limited amount of water.

$$C_6H_5CCl_3 + H_2O \rightarrow C_6H_5COCl + 2\,HCl$$

This series of reactions consumes a large quantity of chlorine. An alternative process uses benzoic acid.

$$C_6H_5CCl_3 + C_6H_5COOH \longrightarrow 2\,C_6H_5COCl + HCl$$

Phosphorous chlorides or iron chlorides are used as catalysts at the solvolytic stage of both processes. Benzoyl chloride can also be made by the reaction of benzoic acid with phosgene, thionyl chloride, or phosphorous pentachloride [15]; chlorination of benzaldehyde, benzyl alcohol, or benzyl benzoate [16]; and direct reaction of benzene with phosgene or the combination of carbon monoxide and chlorine [17].

The benzoyl chloride prepared by the conventional processes may contain trace amounts of chlorobenzoyl chloride, but the product obtained by the reaction of molten phthalic anhydride with hydrogen chloride at 200 °C is free of such impurities.

Uses. Benzoyl chloride is used in making organic peroxides. Benzoyl peroxide [*94-36-0*] and *tert*-butyl peroxybenzoate [*614-45-9*] are widely used as polymerization initiators and as curing agents in the polymer industries. Other uses include intermediates for rubber additives, UV absorbers, dyes, insecticides, and pharmaceuticals.

Specifications. Assay 99.5 % min., *sp* above − 0.5 °C, benzal chloride 0.01 % max., trichlorobenzal chloride 0.01 % max., color (APHA) 10 max.

8.4. Benzonitrile

Physical Properties. Benzonitrile [*100-47-0*], C_7H_5N, M_r 103.12, *mp* −13.8 °C, *bp* 191.1 °C, vapor pressure 1.37 kPa at 70 °C, 2.27 kPa at 79 °C, 4.53 kPa at 94 °C, colorless liquid, almond oil odor, n_D^{15} 1.53056, d_4^{20} 1.0052, solubility in water 1 wt % at 100 °C, miscible with common organic solvents, heat capacity c_p 1.840 J g^{-1} K^{-1}, heat of vaporization 46 kJ/mol, heat of formation −155 kJ/mol, heat of combustion 3063 kJ/mol, flash point 70 °C.

Chemical Properties. Benzonitrile is stable in air and light. In the presence of a strong base or acid, benzonitrile is hydrolyzed to benzoic acid and ammonia (via benzamide). Benzylamine [*100-46-9*] and dibenzylamine can be prepared from benzonitrile by hydrogenation.

Benzonitrile is a powerful solvent. At room temperature it dissolves poly(vinyl chloride), poly(vinyl acetate) resins, polystyrene, polymethacrylate, and nitrocellulose. It does not dissolve polyethylene, polyamide, poly(vinyl alcohol), or fluoropolymers.

Production. Benzonitrile is produced by the high-temperature vapor-phase oxidation of toluene in the presence of ammonia. The traditional catalysts are vanadium and molybdenum, but they suffers from low selectivity and serious decomposition of ammonia [18]. A tungsten – manganese complex catalyst shows better performance [19]. With the latter catalyst, the reaction is carried out in a fixed-bed reactor at 450 °C. The concentration of toluene in the feed stream is 1.5 vol %. The ratio of ammonia to toluene is 4 : 1 with a contact time of 2.4 s. The reaction converts 97 % of the toluene and 30 % of the ammonia. The selectivity is 87.4 %. The crude product, which contains ammonia, hydrogen cyanide, toluene, and high-boilers, is purified by distillation.

Benzonitrile has also been produced from benzoic acid and ammonia in the vapor phase at 400 – 410 °C over alumina [20] or in the liquid phase at 225 – 245 °C [21]. Other methods include liquid-phase ammoxidation of toluene in the presence of a cobalt or manganese bromide catalyst [22], dehydrogenative condensation of benzyl alcohol or benzaldehyde with ammonia, the high-temperature reaction of toluene with nitrous oxide, and cyanation of benzene with cyanogen chloride or dicyanogen.

Uses. The major derivative of benzonitrile is benzoguanamine [*91-76-9*], which is made by the reaction of benzonitrile with dicyanodiamide in the presence of a strong base [23]. Benzoguanamine reacts with formaldehyde and/or alcohols to afford a heat-resistant thermosetting resin.

8.5. Alkyl and Acyl Analogues

Methylbenzoic acids, $C_8H_8O_2$, M_r 136.15.

The physical properties of the methylbenzoic acids are presented in Table 6.

Table 6. Physical properties of the methylbenzoic acids

	mp, °C	*bp*, °C	Density, g/cm^3	Solubility in water 25 °C, wt %	Solubility in water 100 °C, wt %	Solubility in chlorobenzene, 31.8 °C, mol %	Solubility in corresponding xylene, 14 °C, wt %	Heat capacity, J g^{-1} K^{-1}	Heat of fusion, kJ/mol	Heat of combustion, kJ/mol	Heat of formation, kJ/mol	Flash point, °C	Ignition point, °C
2-Methylbenzoic acid	105	259	1.062 at 115 °C	0.118		12.73	6.64	1.285	20.2	3887	−416.5	148 ± 3	495 ± 5
3-Methylbenzoic acid	110	263	1.0543 at 112 °C	0.098		14.07	7.89	1.219	15.7	3886	−426.1	146	
4-Methylbenzoic acid	180	274	1.23 at 20 °C	0.034	1.16	1.76	1.45	1.204	22.7	3880	−429.2	181 ± 1	570 ± 5

The chemical properties of the methylbenzoic acids are similar to those of benzoic acid. They are better preservatives than benzoic acid, but their higher toxicity limits their application. Their alkali metal salts have better anticorrosion effects than benzoates.

2-Methylbenzoic acid [*118-90-1*], *o*-toluic acid, can be produced by the oxidation of *o*-xylene. It is an intermediate for agrochemicals, such as the fungicide mepronil and the herbicide londax.

3-Methylbenzoic acid [*99-04-7*], *m*-toluic acid, is predominantly used for the production of an insect repellant, *N*,*N'*-diethyl-*m*-toluamide [*134-62-3*]. Other uses are as an intermediate for poly(vinyl chloride) stabilizers and agrochemicals.

4-Methylbenzoic acid [*99-94-5*], *p*-toluic acid, is an intermediate in the production of terephthalic acid by oxidation of *p*-xylene. The methyl group of 4-methylbenzoic acid, unlike that of toluene or *p*-xylene, is resistant to oxidation by molecular oxygen with a conventional cobalt catalyst. The addition of bromide overcomes this difficulty. 4-Methylbenzoic acid can be prepared from *p*-xylene by vapor-phase oxidation or nitric acid oxidation. 4-Methylbenzoic acid is used for producing intermediates for antibiotic pharmaceuticals, and organic pigments.

4-*tert*-Butylbenzoic acid [*98-73-7*], $C_{11}H_{14}O_2$, M_r 178.23, crystals, *mp* 168.5–169 °C, dissociation constant 6.99×10^{-7} at 25 °C.

4-*tert*-Butylbenzoic acid is obtained by the liquid-phase air oxidation of 4-*tert*-butyltoluene (prepared from toluene and isobutylene) [24]. It is a modifier for alkyd resins and a polymerization regulator for polyesters. It is also used as an additive in cutting oils and as a corrosion inhibitor. It is hydrogenated to afford the fragrance 4-*tert*-butylbenzaldehyde [*939-97-9*].

2-Benzoylbenzoic acid [*85-52-9*], benzophenone-*o*-carboxylic acid, $C_{14}H_{10}O_3$, M_r 226.23, *mp* 127 °C.

The Friedel–Crafts acylation of benzene with phthalic anhydride is generally used to produce 2-benzoylbenzoic acid. 2-Benzoylbenzoic

acid is principally used for the production of photosensitizers.

8.6. Chlorobenzoic Acids

The physical properties of the monochlorobenzoic acids are listed in Table 7.

2-Chlorobenzoic acid [*118-91-2*], $C_7H_5ClO_2$, M_r 156.57.

2-Chlorobenzoic acid is the strongest acid among the three isomers. Its chlorine atom is easily exchangeable. It is decarboxylated in aqueous solution at 300 °C. With sodium sulfite it gives 2-sulfobenzoic acid. 2-Aminobenzoic acid is formed with ammonia. 2-Chlorobenzoic acid is produced by oxidation of 2-chlorotoluene [*95-49-8*] with molecular oxygen [25] or by the hydrolysis of α,α,α,2-tetrachlorotoluene [*2136-89-2*]. 2-Chlorobenzoic acid is used

for the manufacture of sweeteners, anti-inflammatory pharmaceuticals, and fungicides.

3-Chlorobenzoic acid [*535-80-8*], $C_7H_5ClO_2$. The reactivity of the chlorine atom of 3-chlorobenzoic acid is sluggish compared with the other isomers. Decarboxylation at higher temperatures is insignificant, and it resists oxidation. 3-Chlorobenzoic acid is made by the oxidation of 3-chlorotoluene [*108-41-8*] or by the hydrolysis of 3-chlorobenzoyl chloride [*618-46-2*], which is derived from benzoyl chloride. 3-Chlorobenzoic acid is used for making diphenyl ether type herbicides.

4-Chlorobenzoic acid [*74-11-3*], $C_7H_5ClO_2$ is produced by the oxidation of 4-chlorotoluene [*106-43-4*].

2,4-Dichlorobenzoic acid [*50-84-0*], $C_7H_4Cl_2O_2$, M_r 191.01, *mp* 164 °C, needles, slightly soluble in water.

2,4-Dichlorobenzoic acid is an important pharmaceutical chemical used in diuretics, antirheumatics, and antimalarials. It is produced by the oxidation of 2,4-dichlorotoluene [*95-73-8*], which is obtained by the direct chlorination of toluene.

2,5-Dichlorobenzoic acid [*50-79-3*], $C_7H_4Cl_2O_2$, *mp* 154.4 °C, *bp* 301 °C.

2,5-Dichlorobenzoic acid is made from benzoyl chloride by chlorination and hydrolysis. It is used as a starting material in the production of herbicides.

8.7. Aminobenzoic Acids

Aminobenzoic acids, $C_7H_7NO_2$, M_r 137.14.

The physical properties of aminobenzoic acids are presented in Table 8.

2-Aminobenzoic acid [*118-92-3*], anthranilic acid, was first obtained from indigo by alkali fusion. The methyl derivative is found in essential oils. It is an off-white crystalline powder of sweetish taste, sublimable, and freely soluble in hot water. It has an amphoteric character as a weak acid and a weak base. Therefore, it is soluble in strong acids and bases. It is easily decarboxylated to form aniline.

2-Aminobenzoic acid is usually made from phthalic anhydride via sodium phthalamate.

Oxidative decarboxylation (the Hofmann reaction) is carried out by the addition of sodium hypochlorite solution at 60 – 100 °C followed by acidification.

The product is purified with activated carbon and bisulfite. The overall yield is 88 %. Other synthetic routes include the amination of 2-chlorobenzoic acid and the reduction of 2-nitrobenzoic acid.

2-Aminobenzoic acid is called vitamin L_1; it enhances the milk production of cows. The major use of 2-aminobenzoic acid is as an intermediate for dyes. As its occurrence suggests, it is an intermediate for indigo synthesis. Mordant Brown 40 and Vat Violet 13 are other derivatives. 4-Hydroxy-1-methyl-carbostyril [*1677-46-9*] is an important derivative used in making dyes and pigments. Its methyl and ethyl esters are used as fragrances for toiletries. In the pharmaceutical industry, it is used as an intermediate for tranquilizers and antiphlogistics.

3-Aminobenzoic acid [*99-05-8*] is prepared by the reduction of 3-nitrobenzoic acid and used in dye syntheses. Its derivative *N,N*-dimethyl-3-aminobenzoic acid [*99-64-9*] is also used in the production of dyes.

4-Aminobenzoic acid [*150-13-0*] is widely found in nature as a factor in vitamin B complex. Baker's yeast contains 5 or 6 mg/kg of 4-aminobenzoic acid, and brewer's yeast 10 – 100 mg/kg. It enhances the growth of various microorganisms, and it is essential to the anaerobic metabolism of some bacteria. It is known as bacterial vitamin H and is antagonistic to sulfonamide drugs. It darkens slightly on exposure to air or light. It is slightly soluble in cold water. The pH of a 0.5 wt % aqueous solution is 3.5. It is soluble in ethyl acetate and acetic acid but practically insoluble in petroleum ether.

Table 10. Acute toxicity data for benzoic acid and its derivatives (RTECS)

Compound	Species	Route		Acute toxicity

3-Methylbenzoic acid	rat	oral		$LD_{50} > 5$ g/kg
[*99-04-7*]	mouse	oral		LD_{50} 1630 mg/kg

The conventional method of producing 4-aminobenzoic acid is the reduction of 4-nitrobenzoic acid. The Hofmann degradation reaction of terephthalic acid is another source of 4-aminobenzoic acid. Dimethyl terephthalate reacts with one equivalent of potassium hydroxide in methanol. The resultant salt is then amidated with liquid ammonia in dimethylformamide at 130 – 140 °C to give potassium terephthalamate. This then reacts with sodium hypochlorite solution at 50 – 92 °C. The overall yield is approximately 70 % [26].

[*62-23-7*]	mouse	i.v.		LD_{50} 770 mg/kg
	mouse	i.p.		LD_{50} 880 mg/kg
	rabbit		irritation (eye)	moderate
Hexahydrobenzoic acid	rat	oral		LD_{50} 3265 mg/kg
[*98-89-5*]				

A two-stage Hofmann reaction has been developed. The yield is 93 % [27].

4-Aminobenzoic acid is used principally in the pharmaceuticals industry. Other uses are as a cross-linking agent for polyurethane resins, dyes, and feedstock additives. Ethyl 4-aminobenzoate [*94-09-7*], anesthesin, *mp* 90 – 91 °C is a local anesthetic of low toxicity, irritation, and persistency. It is used especially by dentists.

Folic acid [*59-30-3*], another derivative of 4-aminobenzoic acid, is a hematopoietic vitamin.

8.8. Nitrobenzoic Acids

The physical properties of the mononitrobenzoic acids are given in Table 9.

2-Nitrobenzoic acid [*27178-83-2*], $C_7H_5NO_4$, M_r 167.12, can be prepared by the oxidation of 2-nitrotoluene [*88-72-2*] with nitric acid.

3-Nitrobenzoic acid [*121-92-6*] is prepared by nitrating benzoic acid at low temperature. Approximately 20 % of the 2-nitro isomer and 1.5 % of the 4-nitro isomer are co-produced. The 3-Nitrobenzoic acid can be purified by recrystallization of the sodium salt. The oxidation of 3-nitrobenzaldehyde [*99-61-6*], prepared by

the controlled oxidation of benzaldehyde, gives a higher yield. 3-Nitrobenzoic acid is an intermediate in the preparation of 3-aminobenzoic acid and azo dyes. Its derivative 4-chloro-3-nitrobenzoic acid [*96-99-1*] is an intermediate in the production of dyes.

4-Nitrobenzoic acid [*62-23-7*] is produced commercially by the oxidation of 4-nitrotoluene [*99-99-0*] with molecular oxygen. Oxidation with 15 % nitric acid at 175 °C produces the acid in 88.5 % yield. An interesting method involves the nitration and subsequent oxidation of polystyrene [28]. This method uses the steric hindrance of the polymer chain to improve the *para* to *ortho* ratio of the product.

4-Nitrobenzoic acid is an intermediate for 4-aminobenzoic acid. 4-Nitrobenzoyl chloride [*122-04-3*], mp 75 °C, is a starting material for procaine hydrochloride and folic acid.

8.9. 3-Sulfobenzoic Acid

3-Sulfobenzoic acid [*121-53-9*], *mp* 141 °C, *mp* of dihydrate 98 °C, hygroscopic, soluble in water and ethanol. It is produced by the direct sulfonation of benzoic acid with oleum in ca. 85 % yield. 3-Sulfobenzoic acid is chiefly used for the production of 3-hydroxybenzoic acid [*99-06-9*] by alkali fusion.

8.10. Hexahydrobenzoic Acid

Hexahydrobenzoic acid [*98-89-5*], cyclohexanecarboxylic acid, $C_7H_{12}O_2$, M_r 128.17, *mp* 30 – 31 °C, *bp* 232 – 234 °C, *bp* 150.7 °C at 6.53 kPa, *bp* 120 – 121 °C at 1.87 kPa, d_4^{20} 1.0274, slightly soluble in water, soluble in ethanol and petroleum ether.

Hexahydrobenzoic acid reacts with nitrosylsulfuric acid to produce caprolactam. This is the basic reaction of the toluene-based caprolactam process (→ Caprolactam). Hexahydrobenzoic acid can be oxidized by molecular oxygen at 220 °C in the presence of a copper catalyst [29]. The main products are cyclohexene and cyclohexanone. It can be dehydrocarbonylated in the vapor phase over a heteropoly acid catalyst to yield cyclohexene [30]. Hexahydrobenzoic acid is produced in quantitative yield by the hydrogenation of benzoic acid over noble metal catalysts at 150 – 170 °C, at elevated pressure.

9. Toxicology

Acute toxicity data for benzoic acid and its derivatives are given in Table 10.

Benzoic acid is not accumulated in the human body. After administration it reacts with glycine to form hippuric acid, which is excreted in the urine. The FAO/WHO guideline for the upper limit of daily intake of benzoic acid is 5 – 10 mg/kg. The reproductive toxicity test for rats showed no abnormality.

Benzoic acid has an irritating effect on human mucous membranes. When dust formation is anticipated, protections should be arranged.

Benzoyl chloride is significantly toxic, like other acid chlorides. It irritates mucous membranes strongly (for further data on toxicology, see → Chlorinated Hydrocarbons, Chap. 10.2.6.).

Benzonitrile is less toxic than aliphatic nitriles. It is, nevertheless, absorbed through the skin and may cause convulsions of tissue and paralysis of nerves.

The esters of 4-aminobenzoic acid have a local anesthetic effect. After absorption they stimulate the central nervous system. At the workplace, some of these derivatives may have an allergenic and skin hypersensitizing effect.

4-Nitrobenzoic acid has a significant bactericidal action against *Staphylococci* and *Streptococci*. It is reported to be slightly mutagenic.

6. **Toxicology** 4
7. **References** 4

1. Introduction

In 1838 the parent compound 1,4-benzoquinone (**1**) [*106-51-4*] was prepared by oxidation of quinic acid [*36413-60-2*] with maganese dioxide [1]. More than half a century later its much less stable isomer, 1,2-benzoquinone (**2**) [*583-63-1*] was obtained by silver ion oxidation of catechol [*120-80-9*] [2]. Since then these colorful and reactive compounds have occupied a central place in practical and theoretical studies, which are the subject of two extensive reviews [3, 4]. Other, more specialized reviews are given in [5 – 8]. The chemistry of the quinones includes a vast array of specific reactions and has been explored in great detail, including addition and cycloaddition reactions, photochemistry, biochemistry, oxidative chemistry, and electrochemistry [9 – 19].

1

2

3

While there are many different quinonoid structures by far the most common are **1** and **2**. This article will be restricted to the physical, chemical, industrial, and toxicological characteristics of these compounds and their simple derivatives. The general references provide coverage of many other structural types.

1,4-Benzoquinones can be substituted by a wide variety of alkyl, aryl, halo, oxygen, nitrogen, and sulfur groups. They are usually named as derivatives of **1**, e.g., 2-methyl-1,4-benzoquinone (**3**) [*553-97-9*]. The CAS nomenclature of the quinones, e.g., 2,5-cyclohexadiene-1,4-dione for **1**, is seldom used. Trivial names like *p*-benzoquinone and *p*-tolyquinone (**3**) exist and are used occasionally. Two very useful oxidizing agents are universally known by a trivial name and an acronym: *p*-chloranil [*118-75-2*] (**4**) (2,3,5,6-tetrachloro-1,4- benzoquinone) and DDQ [*84-58-2*] (**5**) (2,3-dichloro-5,6-dicyano-1,4-benzoquinone).

4

5

This lack of widespread concensus concerning nomenclature for the quinones is well illustrated by the latest *Aldrich Catalog Handbook of Fine Chemicals* [20] where one finds: "DDQ, see 2,3-dichloro-5,6-dicyano-1,4-benzoquinone", but "2,5-dichloro-3,6-dihydroxy-1,4-benzoquinone, see chloranilic acid" (**6**), [*87-88-7*]. Thymoquinone (**7**) is still the principal entry for 2-isopropyl-5-methyl-1,4-benzoquinone [*490-91-5*].

6

7

A few compounds with no apparent relationship to quinones continue to be misnamed, e.g., camphorquinone [*10373-78-1*] (2,3-camphandione).

2. Physical Properties

1,4-Benzoquinone (**1**), $C_6H_4O_2$, M_r 108.10, *mp* 113 °C, d_4^{20} 1.318, p_v^{20} 12 Pa, is soluble in most oxygenated organic solvents (ether, alcohol, acetone), and hot ligroin, slightly soluble in pentane, and insoluble in water. Crystallization from alcohol or sublimation produces yellow monoclinic prisms.

1,2-Benzoquinone (**2**), $C_6H_4O_2$, M_r 108.10, *mp* 60 – 70 °C (decomp.), crystallizes in red plates or prisms. It is much less stable than **1**, e.g., it decomposes in water. Compound **2** is soluble in ether, acetone, and benzene, but insoluble in pentane.

2,3,5,6-Tetrachloro-1,4-benzoquinone (**4**), *p*-chloranil, $C_6Cl_4O_2$, M_r 245.88, *mp* 290 °C (sealed tube); and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (**5**), DDQ, M_r 227.01, *mp* 213 – 216 °C are yellow to bright yellow in color and crystallize as monoclinic prisms and plates.

These and most other low molecular mass benzoquinones have high vapor pressures and pungent, irritating odors.

3. Chemical Properties

Many of the quinones found in nature are important as oxidants, and this property is well illustrated in metabolic processes [14, 15] and has found widespread synthetic applications [16, 17]. The cross-conjugated system of two α,β-unsaturated carbonyl groups creates versatile reactivity.

Michael addition has a long and productive history; similar radical and electrophilic reactions offer important alternative and often complementary synthetic routes [9 – 11]. The synthesis of natural products [21] and polycyclic aromatic compounds [22] shows quinones to be important dienophiles for Diels – Alder chemistry. When additions fail to achieve the desired result, substitution reactions are often the route of choice [9 – 11]. There is also a growing literature on the role of quinones in photochemical processes [12].

The addition of arylsulfinic acids to 1,4-benzoquinones has been studied in detail as a model for the more complicated cases of thiol and sulfite anion addition [23]. These other oxidation states of sulfur are interesting in biochemistry [24] and photography [25]. The protonated quinone is the reactive species, a fact that is supported by the product distribution observed with 2-methyl-1,4-benzoquinone (Eq. 1). While 2,5-addition (**8**) is favored by both resonance and molecular orbital arguments, the 2,6-product (**9**) is obtained in a 3:1 ratio.

It has also been shown that the product distribution in this reaction can be strongly influenced by changes in acidity and solvent mixture [26]. Furthermore, the use of ionic liquids shows great promise as "green" solvents [27] in this chemistry. When the acidity or solvent is varied, the relative yields of **8** and **9** can change dramatically [26]. Over the pH range 1 to 4.5 in aqueous buffers one observes the **9/8** ratio changing from 4:1 to 2:3. In a similar fashion this same ratio is 9:1 with absolute ethanol as the solvent and 2:3 when carried out in 50% aqueous acetic acid. This same reaction (Eq. 1) has been studied in ionic liquids [27]. The **9/8** ratio almost exactly reverses to 1:8.5. These interesting media are being promoted as much more environmentally friendly green solvents.

(**8**); b: (**9**)(Eq. 1)

With a single electron-withdrawing substituent 2,3-addition provides the major product [28]. This observation has been exploited as an important route to heterocyclic molecules as illustrated in Equation 2.

(Eq. 2)

The tripeptide glutathione (**10**) adds to 1,4-benzoquinone to form the thioether **11**. Subsequent cross-oxidation and further addition (Eq. 3) give a mixture of the three possible isomeric products [29]. This situation has only been reported once before, and then it also involved the formation of a bisthioether addition product [30].

a: (**10**); b: (**11**)(Eq. 3)

A widely used example of electrophilic quinone chemistry may be described as a tandem reaction of acetic anhydride [31]. The result is the reductive addition of acetate together with esterification. This Thiele – Winter acetoxylation has been used productively, for example, in the synthesis of the antitumor, antibiotic fredericamycin A (Eq. 4) [32].

(Eq. 4)

The Meerwein arylation reaction has been reviewed [33] and support obtained for the importance of the semiquinone radical ion as an intermediate [34]. The synthesis of natural products has involved such radical arylations (Eq. 5) [35].

(Eq. 5)

4. Production of 1,4-Benzoquinone

A variety of quinones are available as fine organic chemicals and most of these are prepared by standard oxidative procedures. Quinones of higher oxidation potential such as chororanil (**4**) (742 mV) or 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (**5**) (ca. 1000 mV) are often the reagents of choice. There are many proposed syntheses of 1,4-benzoquinone, but the oxidation of aniline or phenol remains the practical route. Steam distillation produces a high yield and excellent purity [36]. Glucose is a possible raw material for the preparation of quinones (Eq. 6) [37].

(Eq. 6)

The original preparation of the simplest quinones by oxidation continues to be the principal method for the commercial and laboratory synthesis of quinones [16, 17, 38]. The use of ceric ammonium nitrate for the oxidation of 1,4-dimethoxybenzene derivatives has been used frequently and with great success in the preparation of sensitive quinones. The synthesis of *blattellaquinone* (gentisyl quinone isovalerate) [*849762-24-9*], the sex pheromone of the German cockroach is an important example [39].

5. Uses

Important uses of 1,4-benzoquinone include applications in the inhibition of polymerization, determination of amino acids, and an additive in adhesive mixtures. Additional uses include

research laboratory applications, especially oxidative syntheses, analytical methods, and bactericidal substances. Hydroquinone is important in the photographic, dye, and leather industries and is often prepared from 1,4-benzoquinone. Naphthoquinones are important as vitamin K substitutes, fungicides, and antihemorragic agents.

6. Toxicology

Benzoquinone and many of its low molecular mass derivatives have a high vapor pressure, a penetrating odor, and present a health hazard [40 – 42]. Quinone vapor and the quinone resulting from hydroquinone dust in moist air produce eye injuries that can lead to appreciable loss of vision. The odor of 1,4-benzoquinone is definite at concentrations of 0.1 – 0.15 ppm, and at 0.5 ppm it becomes irritating. Both the MAK and TLV (TWA) are 0.1 ppm and 0.4 mg/m^3; the STEL is 0.3 ppm and 7 mg/m^3 [43, 44]. However, Russia has fixed the threshold limit in air at 0.01 ppm [45]. Both solid quinones and their solutions must be handled with care because they can cause severe local damage to the skin and mucous membranes [46, 47].

The limited carcinogenicity studies on 1,4-benzoquinone conducted with mice and rats do not permit definite classification, and it is listed as a questionable carcinogen. Results for *p*-chloranil are suggestive but inconclusive [48, 49].

1. Introduction

A large number of naphthoquinone and benzoquinone dyes occur naturally as plant constituents, and in the past many of these have found use as colorants. The chemistry of synthetic analogues began with the discovery of *naphthazarin* (**1**) [*475-38-7*] by ROUSSIN in 1861, which was followed ten years later by the synthesis of *naphthoxidine* (the "naphthazarin intermediate") (**2**) [*27823-83-2*] by DE AGUIR and BAYER. Naphthazarin and its derivatives first found use as black chrome mordant dyes for wool and silk. In contrast to the naphthoquinones, synthetic benzoquinone dyes are few in number and are generally of the 2,5-diarylamino-1,4-benzoquinone type, suitable for application as vat dyes, e.g., *Helindon Yellow CG* (**3**) [*4370-55-2*], C.I. 56 005.

From about 1930 onwards, developments in the field of naphthoquinone dyes concentrated on the use of naphthazarin and naphthoxidine as intermediates for the preparation of violet, blue, and green acid and disperse dyes. Perhaps the most successful of these was *Artisil Blue GFL* (**4**), a blue dye for acetate fibers, introduced by Sandoz in 1946. The many developments in this area were reviewed by MERIAN in 1959 [1]. More recently there has been interest in the synthesis and color and constitution properties of simple colored naphthoquinones, stimulated by the fact that such dyes have similar tinctorial properties to the anthraquinones but a smaller molecular size. The naphthoquinones provide a useful alternative to the anthraquinones for certain specialized applications, e.g., as pleochroic dyes with improved solubility for liquid crystal display devices. As a result, research interest in these chromogens remains unabated, even though they have failed to make any major impact as textile dyes.

Details of naphthoquinone and benzoquinone dyes that have been marketed at one time or another may be found in the Colour Index [2], and natural coloring matters of this type have been discussed by THOMSON [3]. Several reviews of naphthoquinone and benzoquinone chemistry have appeared [4 – 8].

2. Benzoquinone Dyes

From the commercial point of view, only the 2,5-diarylamino-1,4-benzoquinones have been of

© 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a03_575.pub2

any significance, e.g., *Helindon Yellow CG* (**3**). These were used as vat dyes for wool and cotton, but are no longer in commercial production. Other examples of early dyes of this type are listed in the Colour Index under numbers 56 000 – 56 050. The inadequate color properties of the amino-substituted benzoquinone chromogen are exemplified by 2,5-bis(dimethylamino)-1,4-benzoquinone [*1521-02-4*], which absorbs at 530 nm in ethanol with an absorption coefficient of only ca. 500 L mol^{-1} cm^{-1}. This low intensity is characteristic of the 2,5-disubstitution pattern. Although other substitution patterns have higher intensities (e.g., the 2-amino derivatives have ε_{max} ca. 5000 L mol^{-1} cm^{-1}), dyes based on these have not been exploited.

More recently the 2,5-diamino-1,4-benzoquinone dyes have found applications other than as colorants. For example, they form stable complexes with *trans*-bis-(triphenylphosphine)phenylnickel(II) chloride, and these have proved to be useful catalysts for the polymerization of ethylene [9]. If 1,4-benzoquinone is condensed with a diamine under oxidizing conditions, polymeric 2,5-diaminobenzoquinones are formed, and these afford excellent anticorrosive coatings for steel [10].

One or both of the carbonyl groups of the 1,4-benzoquinone system have the potential to be replaced by imino groups, but the corresponding dyes have received little attention until recently. 1,4-Benzoquinone monoimines with electron-donating groups (e.g., alkylamino, alkoxy) in the 2- or 2,5-positions provide useful red permanent hair dyes [11]. The color properties of the 2,5-dialkylamino-1,4-benzoquinone diimines are more complex, and show an interesting dependence of color on pH [12]. Thus, the neutral species is yellow, the monoprotonated form red, and the diprotonated form blue.

3. 1,4-Naphthoquinone Dyes

3.1. Simple 1,4-Naphthoquinones

Color can be produced in the 1,4-naphthoquinone chromogen by introduction of amino and hydroxyl groups into the quinonoid ring (i.e., positions 2 and 3), into the benzenoid ring (more particularly positions 5 and 8), or into both rings. The spectroscopic effects of such substitutions have been investigated in detail [13 – 16].

2-Amino-1,4-naphthoquinones are generally yellow to red, with ε_{max} values of ca. 2000 – 5000 L mol^{-1} cm^{-1}, depending on the nature of the substituents attached to the amino group and to the 3-position of the ring. In general, substituents in the 3-position cause a decrease in intensity due to steric crowding, whereas *N*-aryl groups induce a higher intensity. Typically, 2-phenylamino-1,4-naphthoquinone [*6628-97-3*] has λ_{max} 472 nm, ε_{max} 4800 L mol^{-1} cm^{-1}. A now obsolete vat dye of this type is *Helindon Red CR* (**5**) [*3144-89-6*], C.I. 56 050. Fluoro- and trifluoromethylphenylamino analogues have been described for coloring wool and polyester [17].

5

A

B

The 2-pyrrolyl derivatives **A** and **B**, formed respectively by condensation of 1,4-naphthoquinone with N-methylpyrrole [18, 19] and 2,5-dimethylpyrrole [20], can be regarded as vinylogues of the 2-amino-1,4-naphthoquinones. Such compounds have proved useful as direct dyes for hair [19, 20].

The more intensely colored 1,4-naphthoquinones with amino and/or hydroxyl groups in the 5- and 8-positions are analogous to the commercial anthraquinone dyes, but are

generally more bathochromic [14]. For example, 5-methylamino-1,4-naphthoquinone has λ_{max} 529 nm in cyclohexane, whereas 1-methylaminoanthraquinone has λ_{max} 495 nm. This is also true for the 5,8-disubstituted naphthoquinones, but this potential advantage has not proved of commercial significance and few such compounds have been considered as textile dyes. An exception is 5-amino-2,3-dichloro-8-hydroxy-1,4-naphthoquinone (**6**) [*68217-33-4*], which has been claimed as a violet disperse dye for acetate fibers [21]. Naphthazarin (**1**) is an example of a 5,8-disubstituted naphthoquinone of greater value as an intermediate than as a dyestuff.

6

When auxochromes such as −NHR or −OH are present in both rings of the naphthoquinone system, the absorption spectrum consists of two overlapping bands, and this can result in dull colors, typically blue-greys. A 3-cyano group appears to counteract the dulling effect, and **7** [*79469-30-0*] has been described as a blue dye for polyester [22].

7

There is considerable interest in 1,4-naphthoquinones that absorb in the near-infrared, particularly for application in optical recording materials and related high-technology areas. The first simple near-infrared 1,4-naphthoquinone to be described was the 5-amino-2,3-dicyano-8-phenylaminoderivative (**8**, X = H) [*68217-41-4*], which despite its relatively small molecular size has λ_{max} at 770 nm in dichloromethane [14]. The derivative **8** (X = $C_{12}H_{25}$) has been produced as Langmuir – Blodgett films which can be written on with 830 nm laser light with high sensitivity [23]. Other derivatives related to **8** have been patented extensively for optical recording discs [24] and have found commercial use.

8

3.2. Heteroannelated 1,4-Naphthoquinones

A very large number of quinones of the general structure **9** are known, where X corresponds to a heterocyclic residue containing one or more rings, and the chemistry of these has been reviewed extensively [6 – 8]. If X consists of a benzenoid or azabenzenoid ring system, then such compounds are best regarded as anthraquinone analogues. In the case of other heterocyclic residues, they may be considered as 1,4-naphthoquinone derivatives.

9

The simplest members of this group are those where X is a monocyclic residue, such as furan, thiophene, and pyrrole ring systems. Color may then be produced in the usual way by attaching auxochromes to the 5- and/or 8-positions. Few dyes of this type have been suggested for textile applications, presumably because their chemistry is generally more complex than that of comparable anthraquinones. It appears that the color properties of such dyes differ only slightly from those of related anthraquinone structures, as exemplified by studies of imidazole dyes of general structure **10** [25]. However, triazole dyes of formula **11**, where R^1 to R^3 are auxochromes, have been patented as disperse dyes for polyester [26].

10

11

Of greater potential are dyes of general structure **9** in which X corresponds to a polycyclic heterocyclic system, and a large number of these have been examined as possible dyes and pigments. Perhaps the most closely investigated are the *brazanquinones* (**12**), which have been known for more than eighty years. They can be prepared readily by condensing 2,3-dichloro-1,4-naphthoquinone [*117-80-6*] with substituted phenols and naphthols. For example, arylamides of 2-hydroxy-3-naphthoic acid, which are commercially available as coupling components for azoic dye combinations, condense to give yellow and orange vat dyes (**13**) with good substantivity for cotton [27].

12

13

The brazanquinone system has also been used to provide disperse dyes by attaching auxochromes to the benzene ring of the naphthoquinone moiety. Thiophene equivalents of the brazanquinones have received much less attention. Disperse dyes of the type **14** proved to be rather more bathochromic than corresponding anthraquinones, but of lower intensity [28]. Pyrrole analogues have also been neglected, but it is interesting to note that the old dye *Helindon Yellow R* (**15**) [*6451-05-4*], C.I. 56 070, a vat dye for cotton, is the parent compound of this type.

14

15

A different class of polycyclic naphthoquinone dyes is that based on the naphth[2,3-*b*]indolizine-6,11-dione system (**16**), which may be accessed readily by condensation of 2,3-dichloro-1,4-naphthoquinone with active methylene compounds in the presence of pyridine [29], or by reaction of 2-methoxy-3-pyridinio-1,4-naphthoquinone with an active methylene compound [30]. In **16** the bridgehead nitrogen atom acts as an effective auxochrome and thus orange to red colors are observed without further substitution. Derivatives **16** (R = amide group) are of particular value as vat dyes and pigments. Related isomeric heterocyclic structures have also attracted interest, e.g., **17**, a yellow disperse dye for polyester [31].

16

17

As with the simple 1,4-naphthoquinones, research activity in the heteroannelated compounds has been directed towards the development of dyes that absorb in the near-infrared. Noteworthy is the dithiadinaphtho-1,4-naphthoquinone system **18** (X = S), which can be prepared by condensing 2,3-dichloro-5,8-dihydroxy-1,4-naphthoquinone with 2-aminothiophenol [32]. The parent compound **18** (X = S) [*96692-25-0*] shows multiple absorption bands between 400 and 800 nm, with the most intense peak at 725 nm in chloroform (ε_{max} 15 200 L mol^{-1} cm^{-1}) [32]. Oxidation of the sulfur atoms to SO groups produces a large bathochromic shift, and **18** (X = SO) shows a peak at 827 nm (ε_{max} 17 600 L mol^{-1} cm^{-1}) in chloroform [32].

18

4. 1,5-Naphthoquinones

Dyes of this class have the general formula **19**, in which R^1 and R^2 may be hydrogen, alkyl, or aryl groups. Historically and structurally, *naphthoxidine* (**2**) may be regarded as the parent compound; it is a violet-blue compound possessing strong intramolecular hydrogen bonding and exhibiting solubility in organic solvents and in water. This substance and its *N*-substituted derivatives have been represented variously as 1,5-naphthoquinones (**19**) and as the tautomeric 1,4-naphthoquinone imines (**20**). Naphthoxidine itself, for example, is listed under two CAS registry numbers, i.e., [*27823-83-2*] and [*6259-68-3*], for the 1,5-quinone and the 1,4-quinone imine forms, respectively. Although definitive structural evidence has yet to be provided, the generally preferred formulation is the former, and the exceptionally low IR carbonyl frequencies of these compounds (i.e., below 1600 cm^{-1}) support this suggestion. Such a low frequency would be characteristic of a 1,5-naphthoquinone [33], particularly if intramolecular hydrogen bonding were present. Hydrogen bonding in a 1,4-quinone structure such as **20** would not account for such low frequencies, because, for example, 5-amino-1,4-naphthoquinones show absorptions for hydrogen-bonded carbonyl groups near 1630 cm^{-1}. In the following account, the 1,5-quinone structure (**19**) will be assumed.

19

20

Naphthoxidine is a very useful intermediate for dyes of this group, and it can be prepared conveniently by reacting 1,5-dinitronaphthalene with sulfur in oleum.

Procedure [34, 35]. A solution of sulfur (1.25 g) in 20 % oleum (15 cm^3) was added slowly over 35 min to a slurry of 1,6-dinitronaphthalene (2.5 g) in concentrated sulfuric acid (10 cm^3), maintaining the temperature at 50 – 55 °C. The dark brown mixture was stirred for a further 10 min at this temperature and then for 30 min at 20 °C. The mixture was then poured onto ice (200 g) and the suspension filtered. The blue filtrate was made alkaline with sodium hydroxide solution, employing efficient external cooling in order to keep the temperature below 40 °C. The resultant blue precipitate of the sodium salt of naphthoxidine was filtered off and washed with a little water. The solid was extracted with boiling acetic acid, and concentration of the extracts gave lustrous red needles of naphthoxidine (1.44 g, 68 %).

The most successful naphthoxidine-derived dye was *Artisil Blue GFL* (**4**) [*26846-51-5*], which is prepared by bromination of naphthoxidine in acetic acid in the presence of a catalytic amount of iodine or iron. The commercial dye is in fact a mixture of various brominated products, of which **4** is the predominant component. The product is a clear blue disperse dye suitable for acetate and polyester fibers.

Condensation of naphthoxidine with arylamines results in replacement of one or both primary amino groups by the amine, and the resultant *N*-aryl derivatives are greener than **2** and can be used as disperse dyes. An example is *Setacyl Blue Green BS* (**19**; R^1 = 4-ethoxyphenyl, R^2 = H) [1]. Arylamines react directly with **2** in acetic acid, but the reaction is unsuccessful with alkylamines. The latter can be introduced by first reducing **2** to a stable leuco compound with hydrosulfite and then condensing this with the alkylamine. The product is then oxidized to give the quinone dye. It appears that monocondensed dyes have greater affinity for cellulose acetate fibers than the bis-condensation products. Interest in the latter has been stimulated by the discovery that such compounds can provide useful dyes for liquid crystal display devices and exhibit high-order parameters (i.e., contrast ratios). For example, the compound **19** with R^1 = R^2 = 4-methoxyphenyl is a blue-green dye providing an excellent contrast ratio in liquid crystal media [36].

Brominated condensation products can be obtained by using appropriately halogenated naphthoxidine intermediates, e.g., **4**. For example, **4** may be condensed with aniline in acetic acid at 90 °C to give **21** [1]. Naphthoxidine and its brominated derivatives may also be condensed with aminoazo compounds, giving mixed azo – quinone chromogens, e.g., **22**. These are of interest as homogeneous green dyes [1].

21

22

It is possible by modification of reaction conditions to effect the introduction of amino groups into the 2-position of naphthoxidine, but this generally produces dyes with reduced purity of shade and of lower light fastness [1].

As in the case of the 1,4-naphthoquinones, there has been considerable interest in developing near-infrared dyes of this class. The dye **23** [*100012-51-9*] is essentially the 1,5-quinone analogue of dye **18** (X = S) and shows a long-wavelength peak at 750 nm in trichloromethane (ε_{max} 32 000 L mol^{-1} cm^{-1}) [37]. Thus although **23** has the same molecular mass as **18** (X = S), it is both more bathochromic and more intensely absorbing.

1. Introduction

Benzyl alcohol [*100-51-6*] is the simplest and also the industrially most important aromatic alcohol. Liebig and Wöhler first prepared benzyl alcohol from bitter almond oil (benzaldehyde) in 1832 [3]. The structure of benzyl alcohol was determined in 1853 by Cannizzaro [4]. Cannizzaro used the reaction named after him, in which benzaldehyde is disproportionated into benzoic acid and benzyl alcohol through the action of an alkali.

Benzyl alcohol occurs in nature both free and in combined forms. In the latter case it exists as esters of acetic, benzoic, salicylic, and cinnamic acids, among others. It is known to occur in the balsams of Peru and Tolu, in the flower oils of hyacinths and wallflowers, in ylang-ylang oil, and in other essential oils. It also occurs as a glucoside in maize.

2. Physical Properties

Benzyl alcohol, C_7H_8O, is a colorless liquid with a faint aromatic odor and a mildly irritating effect on the mucous membranes.

M_r 108.14, *bp* 205.4 °C at 101.3 kPa, *mp* −15.4 °C, refractive index n_D^{20} 1.5400, density ϱ 1.061 g/cm^3 at 0 °C, 1.045 g/cm^3 at 20 °C, 1.030 g/cm^3 at 40 °C, 1.015 g/cm^3 at 60 °C.

Specific heat 1972 J kg^{-1} K^{-1} at 20 °C, 2135 J kg^{-1} K^{-1} at 50 °C, heat of fusion 82.9 J/g, heat of evaporation 467.0 J/g at 205.4 °C, standard combustion enthalpy 34.58 kJ/g.

Flash point 101 °C, autoignition temperature 435 °C, lower explosive limit (at 170 °C and 101.3 kPa) 1.3 vol %, upper explosive limit 13.0 vol %.

Table 1 shows the vapor pressure in relation to temperature.

Table 1. Vapor pressure of benzyl alcohol vs. temperature

Temperature, °C	Vapor pressure, kPa
60	0.18
80	0.66
100	2.02
120	5.28
140	12.20
160	25.47
180	48.88
200	87.43

Benzyl alcohol is miscible with many organic solvents. At 20 °C, 4.0 g of benzyl alcohol is soluble in 100 g of water and 5.1 g of water is soluble in 100 g of benzyl alcohol. The compositions of several binary azeotropic mixtures are

Diethylaniline	204.2	72.0
Naphthalene	204.1	60.0
p-Cresol	206.8	62.0
p-Bromotoluene	184.5	8.0

Dynamic viscosity η 5.584×10^{-3} Pa · s at 20 °C, surface tension σ 39.96×10^{-3} N/m at 20 °C. Dipole moment μ (measured in liquid benzene) 5.571×10^{-30} C · m (1.67 D), relative dielectric constant ε_r 11.92 at 30 °C, 9.81 at 60 °C.

3. Chemical Properties

The chemical properties of benzyl alcohol are determined mainly by the hydroxyl group. This group shows the typical reactions of aliphatic alcohols (→ Alcohols, Aliphatic). The reactivity of the hydroxyl group is increased by the proximity of the aromatic nucleus. Benzyl alcohol is less acidic than the isomeric cresols and therefore not completely soluble in aqueous alkalis.

If benzyl alcohol is heated in the presence of dehydrating compounds (e.g., aluminum oxide), dibenzyl ether, toluene, and benzaldehyde are formed. Dibenzyl ether is also formed when benzyl alcohol is heated with strong acids or bases. Mixed ethers can be prepared simply through the action of alkyl halides on benzyl alcohol in the presence of bis(acetylacetonato)nickel as a catalyst [7].

Oxidation results in benzaldehyde or benzoic acid, depending on the nature of the oxidizing agent and the reaction conditions. Thus nitric acid as an oxidizing agent gives benzaldehyde [8], whereas solid sodium permanganate monohydrate gives benzoic acid [9]. Under the conditions of the Oppenauer oxidation, benzyl alcohol is oxidized to benzaldehyde in the presence of furfural as a hydrogen acceptor [10]. Benzaldehyde is also formed slowly if benzyl alcohol is exposed to air. Benzyl alcohol can be dehydrogenated in the gas phase using catalysts containing copper or noble metals. The main product of the dehydrogenation is benzaldehyde.

Depending on the reaction conditions, the hydrogenation of benzyl alcohol gives toluene, benzene, methylcyclohexane, cyclohexane, and hydroxymethylcyclohexane.

The reactions between benzyl alcohol and hydrogen halides give the corresponding benzyl halides [11]. Under the conditions for chlorinating the side chains of aromatic compounds, benzyl alcohol forms benzoyl chloride [12].

With ammonia or amines, benzyl alcohol can be converted into *N*-alkyl-, *N,N*-dialkyl-, *N,N,N*-trialkylamines. In the presence of Friedel-Crafts catalysts, aromatic hydrocarbons can be alkylated on the aromatic nucleus. Thus benzyl alcohol and benzene form diphenylmethane, whereas benzyl alcohol and phenol give a mixture of 2- and 4-benzylphenols.

With organic and inorganic acids, acid halides, or acid anhydrides, benzyl alcohol reacts in the normal way to give the corresponding esters. The acid-catalyzed reactions of benzyl alcohol with aldehydes give acetals. The addition of carbon monoxide to benzyl alcohol in the presence of carbonyl catalysts, e.g., rhodium trichloride with benzyl iodide, leads to phenylacetic acid [13].

The treatment of benzyl alcohol with Friedel-Crafts catalysts (e.g., anhydrous aluminum chloride, zinc chloride, concentrated sulfuric acid, or perchloric acid) results in the elimination of water and the formation of resinous products having the composition $H(C_7H_6)_n$ OH and corresponding to the polybenzyl made from benzyl chloride. At temperatures above 150 °C, as little as 1 % hydrogen bromide and 0.04 % iron (II) can cause the exothermic polycondensation of benzyl alcohol to proceed very rapidly. In this reaction the temperature rises to 240 °C, and the sudden pressure increase may be sufficient to break a closed vessel [14]. Thus, for safety reasons, benzyl alcohol should not be heated to temperatures above 100 °C unless it is free from acidic matter and dissolved iron.

4. Production

Benzyl alcohol can be produced in many ways. At present there are only two processes of substantial industrial importance.

1) The hydrolysis of benzyl chloride

2) The hydrogenation of benzaldehyde

4.1. Hydrolysis of Benzyl Chloride

The hydrolysis of benzyl chloride is a reversible reaction which leads to the almost quantitative formation of benzyl alcohol only in the presence of alkaline saponifying agents that combine with the hydrogen chloride as it is formed. It is therefore carried out by heating benzyl chloride with stoichiometric excesses of aqueous solutions of oxides, hydroxides, or carbonates of the alkali or alkaline earth metals. As in the following example, soda is the preferred saponifying agent.

To 610 parts of boiling 10 % soda solution 126.5 parts of benzyl chloride is added with stirring. The reaction mixture is refluxed and stirred until carbon dioxide no longer escapes; this takes an average of five to six hours. An alkali-resistant steel reactor with brick walls is used. The stirrer and heating coil are made of an alloy with a high nickel content. After the reaction mixture has cooled, the upper layer, consisting of crude benzyl alcohol, is removed. The sodium chloride solution below still contains some soda. Dissolved benzyl alcohol can be obtained from it by adding salt or by extracting with benzene or toluene. The crude benzyl alcohol is carefully fractionated at a reduced pressure in an efficient column. The yield is 85 parts of benzyl alcohol and 10 parts of dibenzyl ether.

In the discontinuous hydrolysis of benzyl chloride the reaction time can be reduced by hydrolyzing the final residue of benzyl chloride with sodium hydroxide solution after the saponification with soda solution has been in progress for three hours [15]. The total saponification time required is then only four hours. Normally 8 – 12 % of dibenzyl ether is formed as an unavoidable byproduct of the alkaline hydrolysis of benzyl chloride. Pure dibenzyl ether is recovered by distillation from the residue in the distillation column. The use of alkali hydroxides instead of carbonates reduces the reaction time but favors the formation of dibenzyl ether, which may then exceed 20 % in the crude benzyl alcohol. The percentage of dibenzyl ether can be reduced if the hydrolysis is performed in the presence of an inert solvent, such as benzene, toluene, or xylene.

Benzyl alcohol can be produced continuously if benzyl chloride and the aqueous alkaline solution of saponifying agent react in a flow reactor at an elevated temperature (150 – 350 °C) and sufficient pressure to maintain the reactants in the liquid phase. Thorough mixing of the reactants is important; it can be achieved by the use of suitable baffles in the flow reactor [16] or by maintaining an adequate flow rate [17]. The residence time need then be no more than a few minutes. The mixture emerging from the hydrolysis zone is processed in the normal way. Only a small amount of dibenzyl ether is formed and this can be further reduced by using an inert solvent.

In a new continuous process, benzyl chloride, flowing in one direction, and the alkaline saponifying agent, flowing in the other, are reacted as counter-currents in an inert organic solvent (e.g., toluene, xylene) in a flow reactor. In the extraction zone, the alcohol dissolved in the aqueous alkaline phase is extracted by an inert organic solvent flowing in the opposite direction. Water, likewise as a countercurrent, washes the solution of the crude benzyl alcohol in a washing zone. The flow reactor, extracting zone, and washing zone are integrated in a special apparatus (Fig. 1). The wash water and extract are returned to the hydrolysis zone. This process can be operated at low reaction temperatures (120 – 150 °C) and with a small stoichiometric excess of saponifying agent (5 – 25 %); a small reactor can be used [18].

In a two-step process, benzyl chloride reacts with sodium acetate to form benzyl acetate, which is then saponified to form benzyl alcohol [19]. In a similar process, benzyl chloride reacts with an alkali or alkaline earth formate in the presence of a catalyst to form benzyl formate. The benzyl alcohol is liberated by subsequent

transesterification using an alcohol and a catalyst [20]. Neither of these processes has acquired much importance in the manufacture of benzyl alcohol. However, they could have advantages in the hydrolysis of certain substituted benzyl chlorides that react with soda solution to give dibenzyl ethers and not the desired alcohol.

Figure 1. Hydrolysis of benzyl chloride to form benzyl alcohol in a continuous-flow reactor [18]

4.2. Hydrogenation and Reduction of Benzaldehyde

The industrial production of benzyl alcohol by the hydrogenation of benzaldehyde gained importance because substantial quantities of benzaldehyde were available as a byproduct of the production of phenol (Dow process) and ε-caprolactam (Snia Viscosa process) by the oxidation of toluene (→ Benzaldehyde).

Depending on the reaction conditions, benzaldehyde can be hydrogenated to form benzyl alcohol, toluene, hydroxymethylcyclohexane, methylcyclohexane, and other products. However, very high yields of benzyl alcohol are obtainable if suitable reaction conditions and catalysts are chosen. Raney nickel doped with transition metals [21], nickel or platinum metals with phosphines or phosphine oxides [22], palladium combined with an organic nitrogen [23] or alkali base [24], water [25], or another transition metal [26] can serve as the catalyst. If benzaldehyde is hydrogenated at temperatures of 70 – 200 °C and a hydrogen pressure of 1 – 4 MPa, high yields of benzyl alcohol are obtained in short reaction times. In a well-known continuous process [27], benzaldehyde is hydrogenated to form benzyl alcohol with a high degree of efficiency and a high selectivity in the presence of a platinum–aluminum oxide–lithium oxide catalyst. Stannane [28], sodium hydride [29], zinc [30], and microorganisms [31] can also be used to reduce benzaldehyde to benzyl alcohol, but these processes have no industrial importance. Benzyl alcohol is no longer produced industrially using the Cannizzaro reaction.

4.3. Oxidation of Toluene

The catalytic oxidation of toluene [32] gives only low yields of benzyl alcohol because the reaction conditions support further oxidation to benzaldehyde and benzoic acid. Therefore intermediates are isolated in most benzyl alcohol production processes that start with toluene. The liquid-phase oxidation of toluene with oxygen-depleted air at 170 – 220 °C and pressure sufficient to keep the reaction medium liquid is carried out in the presence of stabilizers for organic hydroperoxides (e.g., sodium pyrophosphate or sodium fluoride). It leads mainly to benzyl hydroperoxide [33] if not more than 10 % of the toluene is permitted to react. The subsequent decomposition of the oxidation product at 165 °C in the presence of soluble cobalt salts yields benzyl alcohol. Benzaldehyde and benzoic acid are formed in fairly large quantities as byproducts. Benzyl hydroperoxide can also be reduced to benzyl alcohol using alkali metal sulfites [34].

The oxidation of toluene as a liquid phase in air is conducted in the presence of acids, acid chlorides, or acid anhydrides; it forms the benzyl esters of these acids. These are then saponified to form benzyl alcohol. For example, the oxidation of toluene in the presence of acetic anhydride at temperatures of 140 – 240 °C and pressures of 1 – 3 MPa yields benzyl acetate [35]. The oxidation is discontinued after 10 % of the toluene has reacted. After the saponification of the oxidation product, 350 g of benzyl alcohol, 55 g of benzaldehyde, and 67 g of benzoic acid are obtained from 500 g of reacted toluene. Phenolic impurities, e.g., cresols, are unavoidably present in the benzyl alcohol obtained by the oxidation of toluene. These impurities can be removed by washing the benzyl alcohol vapor with a countercurrent of alkali benzylate solution in a plate column or a packed column [36].

4.4. Other Manufacturing Processes

The hydrogenation of benzoic acid esters to form benzyl alcohol is of particular interest in cases where benzoic acid esters are formed in substantial amounts. For example, methyl benzoate is formed in the production of dimethyl terephthalate by the Witten process. Catalysts containing copper are preferred. Benzoic acid esters can be hydrogenated to form benzyl alcohol with the aid of a copper catalyst and a carrier consisting of alkaline earth oxides or carbonates [37]. The selectivity can be increased if the catalyst also contains chromium. Temperatures of 100 – 300 °C and pressures above 6 MPa are used.

The hydrogenation of methyl benzoate in the presence of a copper–chromium catalyst is a feature of a three-step process for the production of benzyl alcohol from toluene [38]. The first step is the oxidation of toluene to form benzoic acid. The acid is esterified with methanol in the second step. The hydrogenation of methyl benzoate to form benzyl alcohol is performed in the final step. This process produces benzyl alcohol at an exceptionally low cost.

Ruthenium, rhodium, platinum, and palladium, activated by alkali metal arenes, ketyls, or alkoxides, are catalysts for the hydrogenation of the esters [39]. Using these catalysts, benzoic acid esters can be hydrogenated to form benzyl alcohol under mild conditions and with high selectivity.

Other processes for the production of benzyl alcohol include the hydrogenation of benzoic acid [40], the electrochemical reduction of benzoic acid [41], the hydrolysis of benzylsulfonic acid [42], and the decarboxylation of benzyl formate [43]. These processes have no importance in the industrial production of benzyl alcohol, but they may be used to produce derivatives substituted on the aromatic nucleus. Benzyl alcohol can also be obtained from the benzyl benzoate which is formed in the manufacture of benzoic acid [44].

5. Quality Standards and Test Methods

Several grades of benzyl alcohol are commercially available (Table 3). *Technical* grade is obtained as the first and last fractions in the distilla tion of the crude alcohol, it has little importance. *Pure* benzyl alcohol is the most important grade in terms of volume and is required for most applications. *Double-distilled* benzyl alcohol is used mainly in the perfume and pharmaceutical industries and must therefore be exceptionally pure and free of foreign odors. At 25 °C it forms a clear 4 % aqueous solution. The *photographic* grade normally contains 0.01 – 0.02 % of hydroquinone monomethyl ether to inhibit oxidation.

Gas chromatography using packed or capillary columns is suitable for the quantitative determination of benzyl alcohol. It is more accurate than the method involving acetylation of the hydroxyl group with pyridine and acetic anhydride. Traces of chlorine compounds are unavoidably present in the benzyl alcohol produced by hydrolysis of benzyl chloride. Byproducts, e.g., cresols, may be present in the benzyl alcohol obtained by the oxidation method or via benzaldehyde. Chlorine is quantitatively determined by Wickbold combustion [45], and cresols can be detected by color reactions with aminoantipyrine [36]. Benzaldehyde can be quantitatively determined using hydroxylamine hydrochloride.

The pharmacopoeias of the various countries should be consulted regarding the testing of benzyl alcohol which is to be used in the pharmaceutical industry.

Table 3. Specifications for certain grades of benzyl alcohol (wt %)

Compound	Grades			
	Technical	Pure	Double distilled	Photographic
Benzyl alcohol	> 97.0	> 99.0	> 99.8	> 99.5
Benzaldehyde	< 0.5	< 0.2	< 0.04	< 0.03
Chlorine	< 0.2	< 0.02	< 0.01	< 0.005
Dibenzyl ether	< 2.0	< 0.05	< 0.02	< 0.02

6. Storage, Transportation, and Safety Regulations

Benzyl alcohol is stored in stainless steel tanks. Because benzyl alcohol oxidizes readily, it is advisable to cover the surface of the liquid with nitrogen. Benzyl alcohol can be transported in drums protected by stoving finishes and in tank wagons of aluminum or stainless steel.

Benzyl alcohol belongs to Temperature Class T 2 (autoignition temperature 435 °C). The transportation of benzyl alcohol by rail, road, or water is not subject to special regulations. The labeling of benzyl alcohol must comply with the national and international regulations on dangerous substances.

7. Uses

By virtue of its good solvent properties, benzyl alcohol is an important solvent for surface-coating materials and resins. It dissolves cellulose esters and ethers, alkyd resins, acrylic resins, and fats; it is also used as an ingredient in the inks for ball-point pens. It is added in small amounts to surface-coating materials to improve their flow and gloss. In the textile industry, it is used as an auxiliary in the dyeing of wool, polyamides, and polyesters. Because it has only a relatively faint odor, it is used as a solvent and diluting agent in the manufacture of perfumes and flavors. In color photography it is increasingly important as a development accelerator. In pharmacy it is used as a local anesthetic and, because of its microbicidal effect, as an ingredient of ointments and other preparations.

Benzyl alcohol is a starting material for the preparation of numerous benzyl esters that are used as odorants, flavors, stabilizers for volatile perfumes, and plasticizers. Benzyl alcohol is also used in the extractive distillation of *m*- and *p*-xylenes and *m*- and *p*-cresols.

8. Derivatives

The most important derivatives of benzyl alcohol are dibenzyl ether, benzyl acetate, benzyl benzoate, and benzyl salicylate.

8.1. Dibenzyl Ether

Dibenzyl ether [*103-50-4*], $C_{14}H_{14}O$, M_r 198.27, is a colorless liquid with a faint odor; *mp* 3.6 °C, *bp* 296–298 °C at 101.3 kPa, *bp* 157–158 °C at 1.2 kPa, density ϱ 1.043 g/cm^3 at 20 °C, refractive index n_D^{20} 1.5622, flash point 135 °C. The compound is very slightly soluble in water.

Production. Dibenzyl ether is formed when benzyl alcohol is heated with strong acids or bases. It is produced almost exclusively by the alkaline hydrolysis of benzyl chloride. Heat treatment decomposes dibenzyl ether into benzaldehyde and toluene.

Use. Dibenzyl ether is used as a plasticizer in the surface coatings industry, for special purposes in the rubber and textile industries, and as a solvent for musk and other odorants.

Excess dibenzyl ether can be converted into a mixture of benzotrichloride and benzoyl chloride under the conditions of side chain chlorination with chlorine [46]. Treatment of dibenzyl ether with hydrochloric acid in the presence of trialkyl- or tetraalkylammonium salts gives benzyl chloride [47].

8.2. Benzyl Acetate

Benzyl acetate [*140-11-4*], $C_9H_{10}O_2$, M_r 150.18, is a colorless liquid with an odor of pears and jasmine. It is a constituent of jasmine, gardenia, and other flower oils; *mp* −51.5 °C, *bp* 215 °C at 101.3 kPa, density ϱ 1.056 g/cm^3 at 20 °C, refractive index n_D^{20} 1.5020, flash point 102 °C, very slightly soluble in water.

Production and Use. Benzyl acetate is produced by reacting benzyl chloride with an alkali acetate or by esterifying benzyl alcohol with acetic anhydride. It is also formed in the oxidation of toluene in the presence of acetic acid or acetic anhydride. Benzyl acetate is one of the most used odorants. It is also used as a flavor and, to a small extent, as a high-boiling solvent.

8.3. Benzyl Benzoate

Benzyl benzoate [*120-51-4*], $C_{14}H_{12}O_2$, M_r 212.25, is a colorless, viscous liquid with a pleasant odor. It is the main constituent of Peru balsam, Tolu balsam, and certain flower oils; *mp* 19–21 °C, *bp* 323–324 °C at 101.3 kPa, density ϱ 1.112 g/cm^3 at 25 °C, refractive index n_D^{24} 1.5672, flash point 148 °C, insoluble in water and glycerol.

Production. Benzyl benzoate is produced from benzyl alcohol and sodium benzoate in the presence of triethylamine or by transesterification of methyl benzoate with benzyl alcohol in the presence of an alkali benzyl oxide. In another manufacturing process benzaldehyde is condensed to form benzyl benzoate in the presence of sodium (Claisen-Tishchenko condensation). The presence of a small amount of an aliphatic ether improves this reaction [48]. Benzyl benzoate is a byproduct in the manufacture of benzoic acid by the oxidation of toluene; it is present in the benzoic acid distillation residue.

Use. Benzyl benzoate is used in perfume manufacture, mainly to stabilize volatile odorants. It has vasodilating and spasmolytic effects and is present in many asthma and whooping cough drugs. It is used as an insect repellent and to treat scabies. Benzyl benzoate is used as a plasticizer in the surface coatings and plastics industries.

8.4. Benzyl Salicylate

Benzyl salicylate [*118-58-1*], $C_{14}H_{12}O_3$, M_r 228.25, is a colorless, viscous liquid with a pleasant odor. It occurs naturally in several essential oils; *mp* 24 °C, *bp* 211 °C at 2.67 kPa, density ϱ 1.175 g/cm^3 at 25 °C, refractive index n_D^{25} 1.5787, slightly soluble in water.

Production and Use. Benzyl salicylate can be manufactured by reacting benzyl chloride with an alkali salicylate or by the transesterification of methyl salicylate with benzyl alcohol. It is used as a perfume stabilizer and, because it absorbs ultraviolet light, as an ingredient in sunscreening preparations.

9. Economic Aspects

The benzyl alcohol production capacities of Western Europe and the United States in 1983 were approximately 10 kt and 6 kt, respectively. About 7 kt of benzyl alcohol was actually produced in Western Europe in 1983. Approximately 3.4 kt of benzyl alcohol was produced in the United States in 1979.

10. Toxicology

Benzyl alcohol is used in pharmaceuticals, soaps, detergents, and cosmetics as a fragrance, preservative, and antimicrobial, and is "generally regarded as safe" (GRAS) for use in food by the U.S. Food and Drug Administration. It has industrial applications as a solvent and dye

assistant, but no environmental or workplace exposure limits have been established.

Benzyl alcohol is moderately toxic with acute oral LD_{50} values of 1.2 g/kg in rats and 1.6 g/kg in mice [49]. The LD_{50} for inhalation exposure is approximately 1.0 g/kg (eight hours) in rats [50]. Benzyl alcohol can be absorbed through the skin in sufficient quantities to cause toxicity; the dermal LD_{50} in guinea pigs is < 5 mL/kg [51]. In vitro screening tests for chemical carcinogens in a repair-deficient bacterial strain (P 3478 *E. coli*) were negative [52]. Benzyl alcohol is not considered to be a carcinogen and no data are available regarding teratogenic or reproductive effects.

Benzyl alcohol is widely used as a preservative in solutions of drugs for intravenous administration. The minimum lethal dose in dogs (i.v.) is between 88 and 113 mL/kg of a 0.9 vol % solution of benzyl alcohol in water or in physiological saline solution [53]. Similar doses have been fatal for newborn humans receiving benzyl alcohol in the course of intravenous drug treatment [54]. Benzyl alcohol is estimated to be more than twenty times more toxic than ethyl alcohol (i.v.) [53].

Benzyl alcohol is severely toxic and highly irritating to the eye. Contact with benzyl alcohol causes mild to moderate skin irritation [55]. Hypersensitivity reactions may occur in some individuals with both topical and parenteral administration [56].

Signs of intoxication include vomiting and diarrhea, collapse, central nervous system depression, excitability, muscle paralysis, convulsions, dyspnea, and respiratory arrest [55]. Exposure should be avoided by the use of adequate ventilation systems, self-contained respiration equipment, protective goggles, gloves, and clothing.

Benzylamine (α-aminotoluene) [*100-46-9*] is an important industrially used amine, which is readily available by hydrogenation of benzonitrile or amination of benzaldehyde or benzyl chloride. It also occurs in nature and can be isolated from the leaves of *Reseda media* in small amounts. Benzylamine is a colorless liquid of ammonia-like odor, which is miscible with water in all proportion. It is used in the chemical industry as a starting material for other products or as a corrosion inhibitor. Benzylamine is listed in EINECS 202-854-1, TSCA, and MITI/MO and traded world-wide. It can be transported in steel drums and in high-density polyethylene (HDPE) containers.Benzylamine is harmful in contact with skin and if swallowed. It causes burns, especially when skin is exposed to benzylamine for prolonged periods. Because of the fast reaction of benzylamine and carbon dioxide, slightly leaking flanges or other seals are easily identified by the white solid formed.Benzylamine is produced by Lanxess and other companies and is available in drums, IBC's (intermediate bulk containers), and in bulk.

1. Physical Properties

Benzylamine [*100-46-9*], EINECS 202-854-1, TSCA and MITI/MO listed, α-aminotoluene, phenylmethylamine, moringine, C_7H_9N, M_r 107.16, is a colorless liquid with a weak amine-like odor.

Benzylamine is miscible with water, alcohol, and diethyl ether in all proportions; *bp* 184.5 °C at 101.3 kPa, *bp* 90 °C at 1.6 kPa, solidification point < -30 °C, vapor pressure ca. 60 Pa at 20 °C, ca. 130 Pa at 30 °C, and 520 Pa at 50 °C.

Examples of azeotropic mixtures are given in Table 1.

Heat of vaporization 49 kJ/mol, heat of combustion 4058.7 kJ/mol at 101.3 kPa and 20 °C, refractive index n_D^{20} 1.5401, density d_4^{20} 0.9813, $d_4^{86.6}$ 0.9272, dielectric constant 4.6 at 20.6 °C, electrolytic dissociation constant in water 2.35×10^{-5} at 20 °C, viscosity 1.78 mPa · s at 21.2 °C, 0.295 mPa · s at 178.2 °C, surface tension 38.82×10^{-5} N/cm at 21.1 °C, 31.70×10^{-5} N/cm at 88 °C, autoignition temperature 390 °C, flash point 65 °C, explosion limit 0.9 % (lower) to 14 % (upper); dipole moment (20 °C) 1.18 D (neat), 1.25 D in toluene, 1.29 D in hexane, 1.30 D in cyclohexane, and 1.33 D in benzene [7]; dynamic viscosity 0.01596 g cm^{-1} s^{-1} at 25 °C [8]; absorption maximum λ_{max} in water 255.9 nm (ε 249 L mol^{-1} cm^{-1}) [9], magnetic susceptibility -75.3×10^{-6} cm^3/mol [10].

2. Chemical Properties

Benzylamine is a stronger base than its toluidine isomers and reacts strongly alkaline even if diluted with some water (pH 11.6 in water at 100 g/L) [11]. It forms addition compounds with, e.g., phenol (1 : 3, *mp* 15.3 °C), *p*-cresol (1 : 1, *mp* − 6 °C), and formic acid (1 : 1, *mp* 81 °C). Examples of the salts of benzylamine are the hydrochloride, $C_6H_5CH_2NH_3^+Cl^-$, *mp* 260 °C (decomp.), and the picrate, *mp* 194 °C.

Table 1. Azeotropic mixtures containing benzylamine

Other component, A	*bp* of A, °C	*bp* of azeotropic mixture, °C	Component A in the azeotropic mixture, wt %
Aniline	184.35	186.2	42
Phenol	182.2	196.8	45
m-Cresol	202.2	207.2	56

Benzylamine absorbs carbon dioxide from the air to form the solid carbamic acid salt. If benzylamine is boiled with glacial acetic acid, *N*-acetylbenzylamine is formed. Benzylamine reacts with isocyanates to give substituted ureas, $C_6H_5CH_2NHCONHR$. Benzylamine is nitrated on the aromatic nucleus (8 % *ortho*-, 49 % *meta*-, 43 % *para*-nitrobenzylamine) by nitric acid. Catalytic hydrogenation gives hexahydrobenzylamine, $C_6H_{11}CH_2NH_2$.

3. Production

Benzylamine is produced by the reaction of benzyl chloride with ammonia [12] in aqueous solution. The catalytic hydrogenation of benzonitrile [13 – 15] and the reaction of benzaldehyde with ammonia in the presence of hydrogen and catalysts [16, 17] are alternatives. Both processes use some organic solvent in the reaction mixture.

In the benzaldehyde process, 8 kg of Raney nickel that has been kept under water (corresponding to about 4 kg of 100 % Ni), 10 g of glacial acetic acid, and 110 kg of ammonia are added to a mixture of 250 kg of methanol and 500 kg of benzaldehyde. The resulting batch is hydrogenated in a 1200-L steel autoclave at 100 °C and 15 MPa. The process takes 3 – 5 h. The hydrogen consumed in the reaction is made up at intervals of about 10 min. The contents of the reaction vessel are maintained at the same temperature and pressure for 30 min after hydrogen consumption ends. The catalyst is then separated from the reaction products on a pressure filter [16]. The filtrate contains 470 kg of benzylamine, about 1 kg of benzyl alcohol, less than 1 kg of dibenzylamine, and about 2 kg of Schiff base (*N*-benzalbenzylamine), in addition to methanol, reaction water, and ammonia. The yield is 93 %. Vacuum distillation yields benzylamine of the required technical purity.

Benzylamine has been isolated as a natural compound in the leaves and flowers of *Reseda media* [18].

4. Quality Specifications and Analysis

Commercial benzylamine has an assay of 99 % or more and contains less than 1.0 % water. Depending on the production process, some minor impurities are specified. Color number is typically less than 20 Hazen (APHA; DIN-ISO 6271), and the density at 20 °C 0.98 g/cm^3. For use in the pharmaceuticals industry, some customers require the absence of organic solvents such as benzene, xylene, and chlorinated solvents.

Benzylamine can be analyzed by gas chromatography on commercial columns such as Chrompack CP-SIL 8 for amines or Chrompack WACHS 51 for amines. The results should be corrected for water content.

5. Uses

Benzylamine is used in synthetic textiles, in paints, and as corrosion inhibitor [19]. It is also used as an intermediate in the production of pharmaceutical active substances [21] and compounds for plant and material protection. In this cases benzylamine is often used as “protected nitrogen” [24].

6. Storage and Transportation

For storage and transportation of benzylamine, most types of steel may be used (unalloyed steel, V2A, V4A types; e.g. 1.4301, 1.4306, 1.4571, 1.4401 [DIN 6601]). If chloride or bromide is present, some steel types should be avoided [DIN 6601]. One-tonne containers made from HDPE (Lupolen 4261 A) are also suitable (e.g. Schütz Container, intermediate bulk containers),

as are drums lined with this material. Benzylamine is slowly oxidized on contact with air and forms benzalbenzylamine. It also reacts with carbon dioxide to form its solid carbamic acid salt. It therefore should be stored in a tight closed container for not more than one year. For longer storage, a nitrogen blanket is recommended. In Germany the conditions for storage are classified as 8L (VCI-Lagerklasse) [25]. The handling of benzylamine is shown in a video sequence.

Benzylamine (EC No. 612-047-00-x) is included in the list of substances contained in EC Guideline 67/548, Appendix I and is therefore to be considered a dangerous industrial material. Containers must be marked as follows (EEC Label No. 202-854-1):

C	Corrosive; Benzylamine
R 21/22	Harmful in contact with skin and if swallowed.
R 34	Causes burns.
S 26	In case of contact with eyes, rinse immediately with plenty of water and seek medical advice.
S 36/37/39	Wear suitable protective clothing, gloves, and eye/face protection.
S 45	In case of an accident or if you feel unwell, seek medical advice immediately (show the label where possible).

The following symbols and indications are required on labels and/or transport papers [25]:

Sea (GGVSee/IMDG Code)	Class 8, UN no. 2735, MFAG 320, EmS 8-05, Packing Group (PG) III, Marine Pollutant (MPO): No
Rail/road, Germany (GGVE/GGVS)	Class 8, Item 53C
Rail/road, international (RID/ADR)	Class 8, Item 53C
Hazard symbol	Hazard 080, Compound 2735
Inland vessels (ADNR)	Class 8, Item 53C
Air (ICAO/IATA-DGR)	Class 8, UN no. 2735, PG III

Benzylamine is not allowed to be sent by mail within Germany but can be sent by express mail within Germany if 12 L per package is not exceeded. Declarations are as follows:

Land	UN no. 2735,amines, liquid, corrosive, n.o.s. (Benzylamine), Class 8, Item 53c, ADR (RID)
Sea	UN no. 2735, amines, liquid, corrosive, n.o.s. (Benzylamine)
Air	UN 2735, amines, liquid, corrosive, n.o.s. (Benzylamine)

7. Ecology and Toxicology

Results of laboratory investigations into the ecological behavior of benzylamine are summarized in Table 2 [25].

Table 2. Biodegradability of benzylamine

Method [26]	Degree of elimination	Result
OECD screening test	$> 95\,\%$	readily biodegradable
Sturm test	90 %	readily biodegradable
Zahn – Wellens test	95 %	well eliminated

Benzylamine is readily biodegradable. It is harmful in aquatic environment [German class for hazards in aquatic environment: 1 (weak effect) (WGK 1)]. Acute toxicity: *Pseudomonas fluorescens* (bacteria) 500 mg (EC_0); *Scenedesmus quadricauda* (algae) 6 mg (96-h EC_{10}); *Daphnia magna* 60 mg (48-h EC_{50}); *Leuciscus idus* (fish) 20 mg (48-h EC_0); *Pimephals promelas* (fish) 102 mg (96-h EC_{50}) [25].

Benzylamine causes burns to skin and eyes and may cause sensitization. Rinse immediately with plenty of water. Wash skin also with soap. When used regularly a 5 % aqueous solution of acetic acid should be available for neutralization of contaminated skin. If swallowed dilute by drinking water, rinse mouth. If risk of inhalation is given, use ABEK filters in breathing masks (DIN 3181).

Benzylamine is Ames test negative (no mutagenic effect). Acute oral toxicity: LD_{50} 1130 mg/kg (rat). Acute percutaneous toxicity: LD_{50} 1340 mg/kg (rat) [25]. Toxicity class 3 (Switzerland). All rats inhaling benzylamine for 3 h survived a two-week period (full body exposure). After full body exposure for 5 h, 17 % died.

1. Introduction

Beryllium [*7440-41-7*], Be, is the first element in the second main group of the periodic table. It is a light metal with hexagonal-closest-packed (hcp) structure. Both finely divided metal and the compounds have serious toxic effects on the lungs. In addition to the name beryllium, derived from the mineral beryl, this element with atomic number 4 was formerly called glucinium, chiefly in France, because of the pronounced sweetish taste of its salts.

In 1797 VAUQUELIN [1] discovered beryllium oxide while analyzing varieties of beryl including emerald and aquamarine. WÖHLER [2] and BUSSY [3], working independently, prepared elemental beryllium in 1828 by reduction of beryllium chloride with potassium. In 1899 LEBEAU [4] obtained beryllium crystals by electrolysis of molten sodium beryllium fluoride. Industrial production of beryllium began in 1916 in several countries. The publication in 1916 by OESTERHELD [5] of the phase diagrams of beryllium with iron, nickel, and copper led to the first important use of beryllium in 1931, namely, as an additive, about 2 wt%, in age-hardenable copper alloys [6].

The demand for beryllium increased around 1950 with the development of nuclear reactors because the nuclear properties and low density of beryllium seemed to indicate that the metal would be especially suitable for nonstationary

10.1002/14356007.a04_011.pub2

nuclear reactors of the types used in airplanes, space craft, ships, and submarines [7, 8]. However, beryllium was a disappointment because it swells and becomes brittle when exposed to the simultaneous action of radioactivity and heat [9]. However, the increased research activity in beryllium technology associated with this period produced significant advances in the chemistry, physics, and processing technology of beryllium [7, 10 – 14].

Since the end of the 1950s, there has been increased interest in beryllium as a structural material, especially in aeronautical and astronautical uses because its mechanical and thermal properties relative to weight are superior to those of all other materials [15 – 19]. Most of the beryllium produced today is used for military purposes. Greater use in the civilian sector is hindered mainly by the high price, the toxicity, and the room-temperature susceptibility to brittle fracture of the metal. On the other hand, beryllium oxide is finding increasing use in electrical engineering as an electrical insulator [20]. Beryllium properties, production methods, and applications have been comprehensively reviewed [21].

2. Physical Properties

The properties listed here were measured, for the most part, on commercial grades of beryllium. These contain various impurities and have various grain structures. The most reliable values of the important physical properties of beryllium [10, p. 320], [18, p. 201], [22 – 36] are compiled below. On first glance the most outstanding characteristics of the metal are low density and high melting point.

Atomic number		4
Atomic weight		9.0122
Electronic structure		$1s^2 2s^2$
Atomic radius		112.50 pm
Atomic volume at 298 K		4.877 cm^3/mol
Crystal structures		
hexagonal closest packed at 293 K	*a*	228.56 pm
	c	358.32 pm
	c/a	1.5677
body-centered cubic at 1523 K	*a*	255.0 pm
Melting point		1560 K or 1287 °C
Boiling point		2745 K or 2472 °C
Transformation point		1527 K or 1254 °C

Density at	
298 K	1.8477 g/cm^3
1773 K	1.42
Standard enthalpy	216 J/g
Standard entropy	1.054 J g^{-1} K^{-1}
Heat of fusion	1357 J/g
Entropy of fusion	0.87 J g^{-1} K^{-1}
Heat of transformation	837 J/g
Entropy of transformation	0.186 J g^{-1} K^{-1}
Vapor pressure at	
500 K	5.7×10^{-29} MPa
1000 K	4.73×10^{-12}
1560 K	4.84×10^{-6}
Specific heat at	
298 K	1.830 J g^{-1} K^{-1}
700 K	2.740
Thermal conductivity at 298 K	165 ± 15 W m^{-1} K^{-1}
Linear coefficient of thermal expansion, 298 – 373 K	11.5×10^{-6} K^{-1}
Electrical resistivity at 298 K	4.31×10^{-8} Ω m
Magnetic susceptibility at	
93 K	-0.75×10^{-9} m^3/kg
293 K	-1.00×10^{-9}
573 K	-1.20×10^{-9}
Hall coefficient	2.4×10^{-9} $m^3A^{-1}s^{-1}$
Thermoelectric voltage at 298 K	$\approx 5\times10^{-6}$ V/K
Photoelectric work function	3.92 eV
Compressibility	
isothermal	0.0883×10^{-10} m^2/N
adiabatic	0.103×10^{-10}
Speed of sound	12600 m/s
Surface tension at	
1557 K	1.960 J/m^2
1773 K	1.100
Volume contraction on solidification	3%

The *c*-to-*a* ratio of hexagonal-closest-packed beryllium is very small and decreases with temperature [26]. The existence of the body-centered-cubic high-temperature modification was disputed for many years but has now been demonstrated conclusively [24, 27]. The transformation point is slightly below the melting point [24 – 28]. The sum of the heats of fusion and transformation is given as 1641 J/g, which allows a heat of transformation of 284 J/g to be estimated [28]. However, a much higher value, ≈ 837 J/g, was determined directly [18, p. 201].

The *vapor pressure* values in the literature show considerable variation, probably due to the variable formation of oxide and nitride coatings [37]. They were compiled by Hultgren [28]. The high *specific heat* [28] and *thermal conductivity* [7], [10, p. 320], [31] are noteworthy. Low-temperature measurements show that the thermal conductivity perpendicular to the basal plane is greater than that parallel to the basal plane [38].

The coefficient of *linear expansion* is comparatively low. The values given in the literature vary widely, a fact that can be attributed to differences in grain structure of the samples. This is shown by measurements on single crystals parallel and perpendicular to the basal plane [39] and on highly textured material perpendicular and parallel to the pressing direction [40].

The *electrical resistivity* between 40 and 200 K is significantly lower than that of copper or aluminum [41]. Of course, the differences among the reported values are particularly great for electrical properties [11, 22, 31, 36, 42 – 45] because impurities are especially important here, as has been clearly shown by measurements of residual resistance in materials of different degrees of purity [46, 47]. The information on the superconductivity of beryllium is contradictory. Some investigators [22, 48] have found *superconductivity* at temperatures below 11 K, others [49] have found superconductivity only in thin films below transition temperatures between 7 and 9 K, and still others [45, 50, 51] have been unable to find superconductivity at all.

Beryllium is *diamagnetic;* little work [33, 34] has been reported on the magnetic properties. The available measurements on the thermoelectric force show considerable variation, probably a result of the experimental conditions and sample characteristics [7, 38, 52].

The reflexivity of beryllium is high, particularly in the infrared region [53]. Beryllium transmits x rays well because of its low atomic number. Even relatively long-wave gamma rays cause beryllium to emit neutrons, on account of a (γ,n) reaction. Other nuclear reactions of beryllium and its most important nuclear properties [10, pp. 14, 328], [22, 53, 54] are given below and in Table 1:

Magnetic dipole moment	5.9468 A m^2
Electric quadrupole moment	0.02×10^{-24} cm^2
Binding energy of the last neutron	1.664 MeV
Absorption cross section for thermal neutrons (0.025 eV)	
microscopic (σ_a)	0.9 fm^2
macroscopic (Σ_a)	0.0011 cm^{-1}
Scattering cross section for epithermal neutrons	
microscopic (σ_s)	610 fm^2
macroscopic (Σ_s)	0.76 cm^{-1}

The nuclear reactions of beryllium with fast neutrons and hard γ rays do not result in long-lived radioactivity. However, additional neutrons and gaseous reaction products may be produced. For example, bombardment with 10^{22} fast neutrons per cm^2 generated a total of 23 cm^3 of gas per cm^3 of beryllium: 5% of this gas was tritium, the remainder was helium [56]. The gas was initially located at interstitial sites or at dislocations. Heating at 1170 K caused the formation of gas-filled pores at the grain boundaries and within the grains, which resulted in a decrease in density of 20%. The volume increase due to pore formation begins at about 870 K. In addition to the formation of noble gases and tritium, normal radiation damage also occurs as a result of elastic collisions of fast neutrons with beryllium atoms [7], but the effect of this radiation damage can hardly be separated from the effect of the gas formation.

The moderator and reflector properties of beryllium for thermal and epithermal neutrons are also favorable [8, 9].

3. Mechanical Properties

As in the case of other metals and alloys, e.g., aluminum or brass, the term beryllium is understood to mean a large group of different beryllium grades, whose properties differ to a greater or lesser extent as a result of differences in recovery and processing. This is also the reason for the more or less large ranges for many properties. Nevertheless, the principles of the deformation modes are known, which is the bridge to an understanding of the mechanical behavior of polycrystalline beryllium.

Beryllium *deforms* primarily on basal planes and secondarily on first-order prismatic planes. Slip systems with a nonbasal Burgers vector, e.g., second-order pyramidal slip, are difficult to activate, especially at room temperature. The strong anisotropy of flow stresses on the active slip systems is illustrated in Figure 1. The basal plane has a very low surface energy and hence acts as a cleavage plane. One main reason for the *brittleness* of beryllium is the fact that the basal plane acts both as the cleavage plane and the slip plane [21, vol. I, pp. 7 – 114]. Twinning, which is a very important deformation mechanism in several hcp metals, e.g., zinc, titanium, zirco-

Table 1. Properties of beryllium isotopes

Isotope	Half-life	Radiation, MeV	Source

nium, does not play a similar role in beryllium. In beryllium, twinning acts more as a crack inducer or enhances crack propagation, rather than to increase the deformability.

Figure 1. Flow stress for basal, prismatic, and pyramidal *c* + *a* slip versus temperature [21, vol. I, pp. 7 – 114]
CRSS stands for the critical resolved shear stress.

In polycrystalline beryllium brittle fracture occurs even after comparatively low strain at room temperature [11, 15, 57 – 59].

The reason for this tendency toward brittle fracture is the preferred occurrence of basal slip due to the described strong deformational anisotropy, which induces microcracks [10, p. 372], [60 – 62]. The brittleness can be reduced by purification of the material (e.g., to reduce oxide content) and special thermomechanical treatment (upset forging), which results in a microstructure with a very small grain size [63].

The average *modulus of elasticity* of beryllium is unusually high, 320000 MPa, and is strongly anisotropic [64, 65]: 269000 MPa in the basal plane and 365000 MPa perpendicular to the basal plane [28]. As a result the modulus of elasticity of individual polycrystalline specimens shows considerable variation depending on the type of working, and thus on differences in microstructure (Fig. 2 A). The shear modulus decreases somewhat more rapidly than does the modulus of elasticity as the temperature increases. The Poisson ratio shows a corresponding increase with temperature (Fig. 2 B).

The deformational anisotropy and susceptibility to brittle fracture become lower as the temperature is increased [10, p. 372] so that beryllium is readily workable above 450 K [57]. However, the *elongation* of some commercial grades of beryllium decreases sharply in the temperature range 650 – 900 K, then increas-

Figure 2. Mechanical properties of beryllium as a function of temperature
A) Modulus of elasticity of various grades of beryllium: a) Pressure sintered [66]; b) Cross-rolled cast material [66]; c) Extruded cast material [66]; d) Extruded P/M (powder-metallurgy) material [66]; e) Pressure sintered, 1 wt% BeO [67]
B) Shear modulus and Poisson ratio of cross-rolled cast beryllium [66]

ing again [15, p. 3], [57, 58] (Fig. 3, Curves a, b, and c). This decrease in elongation at intermediate temperatures is caused by impurities. However, when the concentrations of aluminum, iron, and beryllium oxide are adjusted in a well-defined manner, the hot-working characteristics can be greatly improved by effective heat treatment [15, p. 112], [68, 69] (Fig. 3, Curve e). The preferred occurrence of basal slip during warm working, which is usually performed in the temperature range 670 – 1360 K, also results in a pronounced microstructure. This consists of a preferential orientation of the basal planes, e.g., parallel to the direction of extrusion or parallel to the rolling plane [12, p. 240], [15]. The microstructure strongly limits the basal slip at room temperature in the case of deformation parallel to this preferential direction so that the susceptibility to brittle fracture in this direction of deformation is reduced. Considerable elongation can be attained because of the preferred occurrence of prismatic slip. Perpendicular to the preferred direction of the basal plane the potential elongation is almost equal to zero because the direction of prismatic slip lies in the basal plane.

Improvement of the *forming characteristics* by grain refining during melting and casting is possible only to a limited extent [10, p. 136], [12, p. 55], [15, pp. 193, 237, 246], [58, 70 – 72]. The mechanical properties after powder-metallurgical processing are significantly better than those after casting, and material produced by powder metallurgy is now used almost exclusively.

Figure 3. Elongation of various beryllium grades as a function of temperature
a) Cast, extruded [57]; b) Pressure sintered [15, p. 3]; c) Pressure sintered, impurities uncontrolled; d) Pressure sintered, Fe and Al content controlled; e) Pressure sintered, BeO, Al, and Fe content controlled [69]

The susceptibility of beryllium to cleavage fracture is significantly reduced under compressive load so that the deformation values of cast or pressure-sintered material are usually greater than 20%. The buckling strength is comparable to the yield strength; however, the compressive

strength is significantly higher than the tensile strength (Table 2).

Table 2. Strength values, MPa, of extruded beryllium measured in compression test [73]

	Cast		Pressure sintered	
	Room temperature	670 K	Room temperature	670 K
Two-tenths buckling strength	210	179	240	178
Compressive strength	657	460	635	460

4. Chemical Properties

The two 2s electrons of beryllium are valence electrons. The first ionization potential ($Be^0 \rightarrow Be^+ + e$) is 9.32 eV, and the second ($Be^+ \rightarrow Be^{2+} + e$) is 18.21 eV [74]. Although beryllium is almost always divalent in its compounds, it is far more similar to aluminum than to magnesium or calcium [7, 10, 11, 37, 74, 75]. For example, like aluminum, it is amphoteric, and in humid air and water vapor forms a strongly adhering surface layer of oxide that prevents further oxidation up to about 600 °C [37, 76]. Above 600 °C the oxide layer thickens, but oxidation that destroys the metal by break away does not occur below 700 °C.

The affinity of beryllium for oxygen is very great

$$\mathrm{Be\,(s)} + 1/2\mathrm{O_2\,(g)} \rightarrow \mathrm{BeO\,(s)}$$

$$\Delta G^0_T(\mathrm{J/g}) = -66469 + 10.5T \pm 4.7$$

and beryllium is an excellent reducing agent. At temperatures $> 900\,°C$ it reacts violently with nitrogen or ammonia to form beryllium nitride, Be_3N_2. However, beryllium does not react with hydrogen, even at high temperatures, because the formations of the hydrides BeH_2 and BeH, which are difficult to prepare, are endothermic, and the hydrides rapidly decompose at only slightly elevated temperatures. Below 500 – 600 °C beryllium is not attacked by dry carbon dioxide and is attacked only very slowly by moist carbon dioxide. Beryllium powder reacts with fluorine at room temperature, and at elevated temperatures it reacts with chlorine, bromine, and iodine and with sulfur, selenium, and tellurium vapor; in each case, beryllium burns with a flame.

The adhering oxide film protects beryllium from attack by both cold and hot water. It also protects cold beryllium from attack by oxidizing acids [76]. The stability of the film can be increased by addition of dichromate to the water to form a protective chromate layer as in the case of aluminum. Beryllium dissolves in dilute nonoxidizing mineral acids, accompanied by hydrogen evolution and salt formation. In accord with its amphoteric nature it is also attacked by aqueous hydroxide accompanied by hydrogen evolution and beryllate formation. Since most beryllium compounds have a highly exothermic heat of formation, beryllium reduces the salts and the borates and silicates of many metals. For example, the only halides that are stable towards beryllium are those of the alkali metals and magnesium; all others are reduced by beryllium. Molten alkali-metal hydroxides react explosively with beryllium.

Beryllium forms several intermetallic phases with carbon; all transition metals; the alkaline-earth metals magnesium, calcium, and strontium; and the metalloids boron, arsenic, tellurium, etc. [25]. Some of these phases have extensive homogeneity ranges and high melting points [77 – 79]. With very few exceptions, the solubility of metals in solid beryllium and vice versa is very low, even at high temperatures. The binary and ternary beryllium systems were reviewed [21, vol. I, pp. 235 – 305].

Beryllium is very stable towards liquid lithium, sodium, potassium, zinc, magnesium, cadmium, mercury, gallium, indium, tin, lead, antimony, and bismuth. Some of these metals do not dissolve beryllium at all, even at high temperatures, so long as oxygen is not present. If the melts contain metal oxides, the metal oxides are reduced by beryllium with the formation of beryllium oxide. The layer of BeO formed in this way is not adherent and is removed by the melt, so that a fresh surface of beryllium is always available for reduction.

Beryllium is very reactive in the liquid state, reacting with most oxides, nitrides, sulfides, and carbides, including those of magnesium, calcium, aluminum, titanium, and zirconium.

5. Resources, Raw Material

Beryllium is a rare element; its abundance in the earth's crust is about 6 ppm. However, it occurs in concentrated form in various minerals. The total exploitable world reserves of beryllium are estimated at 200000 tons.

The first beryllium mineral commercially exploited was *beryl* [*1302-52-9*], 3 BeO · Al_2O_3 · 6 SiO_2, *mp* 1650 °C, ϱ 2.67 – 2.76 g/cm^3, hardness of 7.5 – 8 on the Mohs' scale, optically negative with weak double refraction, n = 1.57 – 1.60. It crystallizes in hexagonal prisms, which are often very large in size; indeed, crystals weighing several tons have been discovered. It is found in mica schist, granite, pegmatite, and argillite. The crystals often show signs of weathering, and only rarely do they have the ideal composition. Beryl contains about 11% beryllium oxide (4% Be) and is often obtained as a byproduct of feldspar quarrying. The largest deposits are found in Brazil, Argentina, India, Mozambique, Madagascar, Uganda, Zimbabwe, South Africa, and the Former States of USSR. In addition to the aluminum oxide and silicon dioxide, principal impurities in the ores include alkali metals, alkaline-earth metals, iron, manganese, and phosphorus.

Until the late 1960s, beryl was the only beryllium mineral having industrial importance. In 1969 Brush Wellmann Inc. began the processing of *bertrandite* [*12161-82-9*] ores in Utah. This is presently the most important commercial beryllium mineral. Its formula is 4 BeO · SiO_2 · H_2O, but ores contain only 0.2 – 0.35% Be [19, p. 21]. Chrysoberyl, BeO · Al_2O_3; phenakite, 2 BeO · SiO_2; euclase, $BeAlSiO_4(OH)$; and the precious varieties of beryl, emerald and aquamarine, are highly prized as gemstones. About 40 other beryllium-bearing minerals are known.

6. Production

Since the density of beryl is close to that of quartz, concentration by density is not possible. Hand sorting has been the chief means of separation. Flotation is successful only for a few ores [80]. An automatic machine, the Beryl Picker, has been used [81]: the ore is first γ-irradiated to render the beryllium atoms radioactive, $^9Be(\gamma,n)^8Be$. The beryl crystals are then selected out by a sorter guided by a neutron counter [82].

The recovery of beryllium from both beryl and bertrandite includes several stages. The ores are first converted to an acid-soluble form by fusion. Complex chemical processes are then used to obtain comparatively pure beryllium hydroxide or oxide and then beryllium chloride or fluoride. These halogenides are reduced to metallic beryllium with other metals or by melt electrolysis. The beryllium metal obtained is subjected to one or more refining processes and then to further treatment by powder metallurgy or in some cases fusion metallurgy [7, 10 – 12].

6.1. Processing of Beryl

Beryl is treated mainly by the sulfate and fluoride processes. The chloride process is a direct, inexpensive process for recovering beryllium chloride for electrolysis [10, p. 102]. Other processes are not used because of problems with reactions and apparatus [11, 83].

Sulfate Process. First the beryl, which is only slightly soluble in sulfuric acid even under such extreme conditions as heating for several hours in an autoclave at 400 °C, is subjected to either an alkali or a heat treatment.

The *alkali treatment* corresponds to the usual silicate treatment of analytical chemistry: finely ground beryl is heated until fusion or sintered below the melting point with a sufficient quantity of alkaline flux. Suitable alkalies include hydroxides or carbonates of sodium, potassium, and calcium; mixtures of these carbonates; calcium oxide; borax; lead chloride; and sodium sulfate and charcoal. The mechanism of the fusion is still not fully understood [84]. The ratio of flux to beryl depends on the operating conditions, especially the temperature: the higher the temperature the less flux. For alkali treatments involving molten material, gas-heated or oil-heated rotary furnaces or blast furnaces are suitable. Rotary kilns, muffle furnaces, or tunnel kilns are used for sintering.

In the *heat treatment* the beryl is melted (*mp* 1650 °C) without additives and then quenched in water. After this treatment about 50 – 60% of the beryl has a greater solubility in sulfuric acid.

The rest of the beryllium oxide forms a solid solution with silicon dioxide that is not attacked by sulfuric acid. At 900 °C this solid solution separates into its components, and a heat treatment at this temperature produces a free beryllium oxide that is soluble in sulfuric acid. Such a two-stage heat treatment renders a total of 90 – 95% of the beryl soluble.

The heat-treated beryl is extracted with hot concentrated sulfuric acid, whereas alkali-treated beryl is extracted with cold sulfuric acid. In the second case there is no heating cost, but the total consumption of acid is greater because of the alkali added. The liquor is diluted with water, and the insoluble silicon dioxide separated by filtration. At this point the filtrate contains not only beryllium and aluminum sulfate but also considerable quantities of iron sulfate and smaller amounts of other impurities, all of which must be removed before precipitation of beryllium hydroxide. Examples of the many separation methods [11] include the alum separation, the ammonium carbonate separation, and the chelate separation.

In the *alum separation* excess ammonium or potassium sulfate is added to the hot sulfate solution. Upon cooling, all the aluminum precipitates as alum and can be separated from the beryllium sulfate solution in a centrifuge. The filtrate is diluted and then oxidized with potassium permanganate. It is then heated to the boiling point, and calcium carbonate slurry is added until a pH of 3.8 – 4.2 is reached. This causes iron and manganese to precipitate as the hydroxides and calcium to precipitate as calcium sulfate dihydrate. The beryllium hydroxide is then precipitated by addition of ammonia.

In the *ammonium carbonate separation* the liquor obtained from the fusion treatment is treated with saturated ammonium carbonate solution to precipitate aluminum, iron, and other heavy metals as hydroxides, which are then separated by filtration. The filtrate, which contains the soluble beryllium hydroxide, is concentrated by boiling to precipitate readily filterable sparingly soluble basic beryllium carbonate, which is converted to low-density beryllium oxide by calcining at low temperatures.

In the *chelate separation* iron and aluminum are chelated, e.g., with ethylenediaminetetraacetic acid. The beryllium can be precipitated as hydroxide, while these complexes remain in solution.

If the separation process does not lead directly to fine-grained, readily filterable beryllium hydroxide or oxide, the fusion liquor is adjusted to pH 7.5 with ammonia or sodium hydroxide and then heated to 95 – 98 °C. A crystalline, readily filterable beryllium hydroxide is obtained under these conditions. At lower pH gelatinous hydroxide is obtained; at higher pH, amorphous hydroxide is obtained [11]. If the temperature is too low, the crystalline hydroxide forms too slowly.

Brush Wellman Inc., the world's largest beryllium producer, has fully automated its process, called the *caustic process*. This process uses a heat fusion treatment and is characterized by low consumption of sulfuric acid, reliable separation of iron and other heavy metal impurities by combined alum and chelate separation, and recovery of an easily filterable beryllium hydroxide by hydrolysis of the sodium beryllate [10, p. 71].

Fluoride Process. In the fluoride process beryl is melted or sintered at ≈ 700 °C with sodium hexafluorosilicate. Only the beryllium oxide is converted to a water-soluble salt; aluminum oxide, silicon dioxide, and other impurities are essentially unattacked [83, 85]:

$$2(3BeO \cdot Al_2O_3 \cdot 6SiO_2) + 6Na_2(SiF_6) \rightarrow 6Na_2BeF_4 + 2Al_2O_3 + 15SiO_2 + 3SiF_4$$

The formation of other beryllium salts ($NaBeF_3$, BeF_2) is not observed. Water-soluble Na_3AlF_6 may also be formed in small amounts.

Other suitable extracting agents are hydrogen fluoride at 630 °C, molten fluorides, other fluorosilicates, or silicon tetrafluoride [86]. Rotary kilns are used for reaction with the gases; the solid mixtures are briquetted and sintered in muffle furnaces or tunnel kilns.

The sodium hexafluorosilicate needed for the fluoride process is relatively expensive. However, consumption can be greatly reduced by adding sodium fluoride [87] or sodium carbonate [88], which traps and thus "recycles" the liberated silicon tetrafluoride.

The sodium fluoride remaining in solution after precipitation of the beryllium hydroxide can

also be recovered. Sodium hexafluoroferrate(III) is obtained by precipitation with iron(III) sulfate [89] and can be used instead of sodium hexafluorosilicate.

The reaction product must be leached with water at room temperature because silicon dioxide is attacked by fluoride solutions at elevated temperatures. On the other hand, the leaching must be performed as rapidly as possible because otherwise the beryllium salt that is already dissolved will precipitate [11] and in this form it is sparingly soluble, unlike the form which is present in the original fusion product. In order to obtain beryllium hydroxide the solution is made alkaline with NaOH. Beryllium hydroxide precipitates when the solution is diluted with water and then boiled. The fluoride process is being tested in a pilot plant by Bhabba Atomic Research Centre, India [90].

Chloride Process. At temperatures above 630 °C the components of beryl can be extracted in a stream of chlorine; reducing conditions greatly enhance the yield:

$$3BeO \cdot Al_2O_3 \cdot 6SiO_2 + 18Cl_2 + 18C \rightarrow 3BeCl_2 + 2AlCl_3 + 6SiCl_4 + 18CO$$

In practice a mixture of pulverized beryl and carbon is either heated near 800 °C in a stream of chlorine [91, 92] or melted in an electric-arc furnace. In the second case the carbides that form are chlorinated [93, 94]. The reaction can also be carried out with gases that contain chlorine, such as hydrogen chloride [83], carbon tetrachloride [95], sulfur chloride [83], or phosgene [96, 97]. The volatile chlorides are separated by fractional condensation or liquid – liquid extraction with sulfur dichloride, sulfuryl chloride, phosphorus trichloride, phosphorus oxychloride, boron chloride, carbon tetrachloride, or phosgene [83].

Reducing chlorination of the beryllium hydroxide or oxide obtained in the sulfate or fluoride process gives beryllium chloride, the starting material for the electrolytic production of beryllium.

6.2. Processing of Bertrandite

The beryllium-poor bertrandite ores ($\leqq$ 0.5 – 0.8% BeO) discovered in the United States in 1960 cannot be economically smelted by conventional methods. A new process was therefore developed by Brush Wellman Inc., called the *SX-Carbonate process* (Fig. 4) [98, 99]. This process produces a very pure beryllium hydroxide (Table 3) by liquid – liquid extraction with organic phases [74].

Table 3. Typical analyses of beryllium hydroxide obtained by two processes, ppm, with respect to BeO [98, 99]

Element	SX-Carbonate process	Caustic process
Al	200	3 000
Fe	200	1 300
Cr	50	125
Li	70	300
Mg	100	6 000
Mn	10	900
Ni	10	30
Na	500	10 000
Ca	200	800
Cu	5	25
Si	100	1 500
Zn	20	700

Unlike beryl, bertrandite is soluble in sulfuric acid without pretreatment. The insoluble residue (SiO_2, etc.) and the aluminum content, which precipitates as an aluminum alum, are removed. The sulfate solution, pH = 0.5, then contains the beryllium and also aluminum, calcium, iron, sodium, and traces of other elements.

The sulfate solution is extracted with a 0.3 m solution of ammonium di-2-ethylhexyl phosphate/di-2-ethylhexyl phosphoric acid/kerosine (DAP) in a five-stage mixer at ≈ 50 °C. In the first mixer the pH is about 2, and after the last stage it is about 5.5. The acid strength is adjusted in a well-defined manner in each stage by means of the ratio of the ammoniacal to the acid component of the organic phase. Beryllium, aluminum, and iron enter the organic phase almost quantitatively, while the other impurities remain in the sulfate solution. Following separation of the two liquid phases, the metal ions are removed from the organic compounds by a 3.0 – 3.5 m ammonium carbonate solution in a two-stage mixer. This results in the formation of a basic beryllium carbonate solution, which is actually a slurry since it contains precipitated aluminum hydroxide (the ABC slurry). The organic phase, which is now free of metal ions, is returned to the process after purification. Iron is

Figure 4. Flow diagram of the SX-Carbonate process (Brush Wellman Inc., USA) [98, 99]
DAP is the abbreviation for the solution ammonium di-2-ethylhexyl phosphate – di-2-ethylhexyl phosphoric acid – kerosine.

precipitated from the ABC slurry by heat treatment, 45 min at 85 °C, and filtered off with the aluminum hydroxide. The beryllium remains in solution as basic carbonate. The specified time must be observed as closely as possible: if the heat treatment is too short, iron is only partially precipitated. If it is too long, the beryllium loss will be too great. Even so, about 2% of the beryllium is coprecipitated and about 4 – 6% is contained in the hydroxide filter cake. Half of the beryllium can be separated by careful washing. The remainder is recovered by dissolving the precipitate in sulfuric acid, extracting the iron with an organic phase, and recycling the beryllium- and aluminum-containing sulfate solution to the process before the alum precipitation.

The basic beryllium carbonate solution separated from the ABC slurry by filtration is decomposed in an autoclave (140 – 160 °C, 1.0 – 1.4 MPa) into ammonia, carbon dioxide, and a beryllium hydroxide that is easily filtered off and that is quite pure (Table 3). The ammonia and carbon dioxide are used to produce ammonium carbonate, which is returned to the process. The ABC slurry can be treated additionally to further reduce the concentration of impurities, e.g., to reduce the iron content to less than 50 ppm. For this reason beryl ores are today also treated by the SX-Carbonate process, following the usual heat treatment.

6.3. Production of Reducible Compounds

The most important metal production processes are based on reduction of beryllium fluoride by magnesium and beryllium chloride by melt electrolysis. Therefore, the beryllium hydroxide or oxide obtained from the fusion process must be converted into one of these halides.

Beryllium Fluoride. First beryllium hydroxide is dissolved in an ammonium hydrogen fluoride solution. The resulting ammonium tetrafluoroberyllate is dissociated to such a small extend in the solution that the pH can be varied over a wide range without beryllium hydroxide precipitating. Impurities can thus be precipitated relatively easily as hydroxides. Aluminum is precipitated as hydroxide by increasing the pH to 8.3. Chromium and manganese are precipitated by oxidation with lead dioxide, and manganese is precipitated by oxidation with lead dioxide and manganese dioxide. Copper, nickel, and lead are precipitated as sulfides.

Ammonium tetrafluoroberyllate is freely soluble in water. When concentrated by evaporation, it crystallizes without water of hydration. Above 130 °C it dissociates into ammonium fluoride and beryllium fluoride. Between 900 and 1100 °C ammonium tetrafluoroberyllate dissociates into gaseous beryllium fluoride and gaseous ammonium fluoride. The latter can be recycled to the process as ammonium hydrogen fluoride by dissolution in aqueous hydrogen fluoride. Cooling produces beryllium fluoride as vitreous grains [10, p. 71], [100].

Beryllium Chloride. Beryllium chloride can be prepared either directly from beryl by the chloride process or by chlorination of beryllium oxide under reducing conditions [101].

Beryllium chloride is especially well suited for purification by distillation in a stream of hydrogen [10, p. 102] and fractional condensation [102]. The significantly lower-boiling chlorides of aluminum, silicon, and iron(III) can be separated by careful temperature control. Iron(II) chloride, which is reduced by hydrogen, stays in the residue.

6.4. Metal Production

The chief difficulties involved in the production of beryllium metal are the reactivity and high melting point of the metal and the extreme stability of the oxide. Of the many possible methods of producing beryllium [10, 11, 84] two are used in industry presently: fusion electrolysis and reduction of halides by metals.

Only calcium is able to reduce the extremely stable beryllium oxide directly under standard conditions. However, calcium forms the very stable intermetallic compound CaBe [103]. Reduction of BeO with titanium, zirconium [104], or carbon [105] at high temperatures is theoretically possible: the volatile beryllium would have to be distilled off from the reaction zone immediately. However, this method is not used.

Reduction with Metals. The most important industrial process is the reduction of beryllium fluoride with magnesium [10, p. 71], [106 – 109], the process presently used by Brush Wellman Inc.

The reaction is started by heating a mixture of relatively coarse-grained beryllium fluoride and magnesium in a graphite crucible. At a temperature of about 1300 °C the reaction produces a mixture of beryllium pebbles and magnesium fluoride. The reaction cannot be performed without external heating because the heat of reaction is not great and because the beryllium fluoride must be processed in the form of relatively large particles due to its toxicity and hygroscopicity. Normally about 70% of the stoichiometric quantity of magnesium is used. In this way a readily water-soluble beryllium magnesium fluoride slag, easily separated from the coarse-grained beryllium, is produced. The unreacted beryllium fluoride is separated from the magnesium fluoride and returned to the process.

The reaction of beryllium chloride with magnesium or sodium or the reaction of beryllium fluoride with sodium cannot be carried out in the same way. Sodium is more difficult to work with because of its low boiling point and its reaction with graphite. Beryllium chloride (*bp* 520 °C) is too volatile. The reduction of beryllium chloride with sodium in the vapor phase at 250 °C is the only process developed to the production stage [110 – 112]. However, this process has no economic importance.

Fusion Electrolysis. All practical electrolytic methods of production are based on the decomposition of beryllium fluoride, beryllium oxide, or beryllium chloride mixed with halides of the alkali metals or alkaline-earth metals [83]. These main group I and II halides are necessary to form a stable melt electrolyte with good conducting properties — the molten beryllium halides are covalently bonded and thus poor electrical conductors. In addition, only beryllium fluoride has a sufficiently large

interval between melting point and boiling point at atmospheric pressure.

The electrolysis of the fluoride was developed by A. Stock, H. Goldschmidt [113], Siemens & Halske [114], and the Beryllium Research Society. The electrolysis was carried out above the melting point of beryllium, at 1290 – 1400 °C. These methods and the similar methods of J. Dickinson [115] and A. C. Vivian [116] are now obsolete.

The electrolysis of beryllium chloride [117] can be carried out at temperatures so low that the metal neither melts nor oxidizes. The beryllium is obtained as solid flakes, which are separated by washing out the electrolyte.

Mixtures of approximately equal parts of beryllium chloride and sodium chloride are electrolyzed at ≈ 350 –400 °C. The composition of the electrolyte is held as constant as possible. The apparatus consists of two identical nickel vessels hanging in electric furnaces. The crucible covers are fitted with the connections. One of the covers contains the anode and can be placed alternately on each crucible; the crucibles themselves serve as cathodes. During electrolysis (4 – 6 V, 0.08 A per cm^2 of cathode surface area) the metal is deposited as flakes on the cathode wall. When the beryllium chloride concentration in the melt has fallen to 45 wt%, the melt is siphoned into the second crucible, in which beryllium chloride and sodium chloride have previously been melted down in quantities corresponding to the quantities consumed by the electrolysis in the first crucible. In this way the bath is again given its original composition. The crucible covers are then exchanged, and electrolysis is started in the second crucible. The chlorine generated at the anode during electrolysis is collected and used in the production of beryllium chloride.

The equipment for this process was developed by Degussa. Since the Second World War this process has been used by Pechiney Cie. Chloride electrolysis was also used in France by Trefimetaux G.P., a joint subsidiary of Pechiney Cie. and Kawecki Berylco Ind. Inc., and by NGK Insulators in Japan. It was used in slightly modified form by Murex Ltd., England [10]. It was also used in the Soviet Union [118].

6.5. Refining and Further Processing

The as-reduced beryllium pebbles or flakes still contain many impurities and have to be refined before they are used to fabricate structural pieces. The main impurities in electrolytic beryllium are sodium and chlorine. The main impurities in beryllium from the magnesium reduction process are magnesium and magnesium fluoride. Other impurities include beryllium oxide, carbon, and metals, the most important being aluminum, iron, and silicon. Typical analyses of magnesium-reduced beryllium and electrolytic beryllium (CR flakes, Pechiney Cie.) are given in Table 4. Some of the impurities have adverse effects on the mechanical properties and corrosion of beryllium or are reactor poisons. Commercial grades of beryllium are refined exclusively by vacuum melting in beryllium oxide or magnesium oxide crucibles and casting in graphite ingot molds. The ingots weigh ≈ 200 kg. Their surfaces are machined (skinned) to remove the high carbon content material adjacent to the mold wall.

Table 4. Composition of beryllium produced by various methods, ppm [12]

Element	Mg-reduced, coarse-grained	Electrolysis	
		CR flakes	SR flakes
O	–	2300	500 – 800
Al	400	<200	60
Fe	500	300	50
Ni	100	150	30
Si	50	75	30
B	–	2	2
Cr	100	20	5
Mn	100	60	30
Ca	–	200	30
Mg	15000	50	30
Na	–	300	–
C	300	300	150
F	20000	–	–
Cl	–	1000	700
Be, wt%	96.0	96.5	99.87

The melting of magnesium-reduced beryllium in a high vacuum produces a degree of purity comparable to that of electrolytic beryllium. Melting the electrolytic flakes in a vacuum further reduces the content of halides and low-boiling metals. A very pure grade of beryllium, particularly with respect to the content of oxide, aluminum, iron, silicon, carbon, and halides, can be produced by electrolytic purification (SR

flakes, Pechiney Cie.). Other methods, such as vacuum distillation [10, 11, 18, 119 – 123], zone melting [18, 47, 124, 125], or liquid-metal extraction [18] have been used in the laboratory only.

Melting and Casting. The main purpose of melting and casting of beryllium is purification (see above); the production of semifinished goods is of secondary importance [12, p. 55]. The reason for this is that parts produced from castings have significantly poorer properties, even after working, than parts made by powder metallurgy. Cast flaws due to gas evolution during solidification and transcrystalline microcracks [10, p. 136], [15, p. 677] caused by cooling stresses cannot be prevented, even though they can be greatly reduced by mold design and construction [126]. Another significant disadvantage is the coarse-grained texture that develops during solidification, resulting in poor mechanical properties not improvable by thermomechanical treatment [10, p. 136], [12, p. 55], [15, pp. 193, 237, 246], [71, 72]. Fairly often crystals several centimeters in length are observed after induction melting [12, p. 55], and often crystals several millimeters in length are observed after electric-arc melting [15, pp. 677, 687], [126]. No effective grain-reducing agent is known [126].

Powder Manufacture. Beryllium was first worked by powder metallurgy in 1946. Since then many methods of powder production and compaction capable of producing ductile beryllium parts with good high-temperature strength have been studied and tested [12], [21, vol. 2, pp. 13 – 29], [127]. However, the concentration of impurities is increased during powder-metallurgical working. Atmospheric oxygen and nitrogen, as well as iron and carbon from the mechanical working of the material into powders, are especially important. Above all, there is an increase in the oxide content as the grain size is decreased, i.e., as the specific surface increases. On the other hand, the oxide is desirable in certain circumstances because it increases strength and inhibits grain growth.

Powder manufacturing starts with cast ingots of inherently coarse grain size characterized by low ductility and resistance to fracture. These ingots are chipped with a lathe. The equipment is heavy duty: a multipoint tool can chip a 65-kg ingot in a single pass. These relatively coarse chips must be ground, or otherwise comminuted to finer particle sizes.

The first milling method commercially employed was *rotary grinding* between one stationary water-cooled and one rotating beryllium disk. The coarse chips were fed through a central hole in the stationary disk, and the fine powder emerged peripherally. The mill was enclosed into a sealed system to minimize contamination of the powder and to protect the environment from the toxic beryllium dust. This method was the standard for many years. Almost everywhere it has now been replaced by the impact attrition mill.

Within the *impact attrition mill* the coarse powder is fed into a gas stream, accelerated through a nozzle and impacted against a beryllium target. The morphology of the powder particles comminuted by this process is more spherical and less flat than disk-milled powder. Therefore, the mechanical properties of impact-ground powder compacts are more uniform. Because of the improved isotropy and a lower amount of inclusions and impurities the elongations of beryllium grades produced from impact-attrition material are higher.

Another commercial production process is *ball-milling*. It is used for high-oxide ultrafine powder ($\approx 5\ \mu m$), which is made especially for instrumentation uses. The high microyield strength specified for such qualities is provided by the fine particle size and the high oxide content that strengthen the grain boundaries within the unpacked material. Because ball-milled powders are flat, like the particles produced by rotary grinding, they are difficult to handle and cause anisotropic physical and mechanical properties in the compacted beryllium billets.

Other powder production methods, like fluid-energy milling, disintegration of beryllium melts by gas atomization, rotating electrode process, or centrifuged shot-casting, have been used only in the laboratory [21, vol. 2, pp. 13 – 29]. Nevertheless, some of these processes may be used to produce commercial beryllium powder within the foreseeable future.

Powder Consolidation. *Vacuum hot pressing* of beryllium powder in graphite or steel dies

is by far the most important commercial consolidation process. The powder is either dynamically compacted in the die or prepressed under cold isostatic conditions. After the die has been heated to 1000 – 1200 °C, a pressure of 1.4 –10 MPa is applied. In this way billets up to 1.80 m in diameter and 6 t in weight, with relative density of nearly 100%, have been manufactured.

Hot isostatic pressing is used to produce more complicated parts with improved isotropic properties. The powders are either directly consolidated in a one-step process or preconsolidated. In preconsolidation the powder is prepressed at 210 – 700 MPa under cold isostatic conditions in rubber containers, the cold compact degassed at 650 °C, and the compact pressed isostatically for 2 – 3 h at 70 MPa and ≈ 760 °C in evacuated stainless steel containers [128].

The combination of *cold pressing and sintering* has been applied in the production of special parts, e.g., aircraft brake segments. Preforms may be sintered using mandrels to limit distortion and give better shape control. Sintering is usually carried out in a vacuum, which ensures better consolidation and higher densities than those achieved in argon.

The hot-pressed ingots are worked into semifinished goods or finished parts by machining, rolling (760 – 870 °C), extrusion (900 – 1090 °C), drawing (400 – 430 °C), deep-drawing (710 –760 °C), forging, and compression (400 – 430 °C) [13, 14].

During hot deformation the beryllium is usually enclosed in a steel container. Working with such "canned" material greatly simplifies the operation because the workpieces need not be in a vacuum and need to be heated only slightly or not at all. The steel cover reduces oxidation and surface damage, improves lubrication, and produces a uniform temperature distribution in the workpiece. Although hot-deformed parts are usually less expensive than machined parts, they have highly anisotropic properties, with the favorable values in the direction of material flow during deformation and the less favorable values perpendicular to this direction. Cross-rolling produces uniform properties, e.g., in the sheet plane. Other processes used only in special cases are slip casting [21, vol. 2, pp. 13 – 29], [127, 129, 130], spark sintering [131], sinter forging [12, p. 102], [132], plasma injection [133], and isostatic hot-pressing [128].

Production of Single Crystals. The first comprehensive work on beryllium single crystals was done in the early 1950s [10, p. 372], [134 – 137]. These crystals were used mainly for investigations of the mechanical and cleavage fracture behavior of beryllium and were produced only in the laboratory. They were grown by slow solidification from the melt in a crucible [10, p. 372], [137], direct crystallization from vapor [138], and crucibleless zone melting [134, 139 – 145]. Efforts to produce beryllium single crystals using the Bridgeman method were unsuccessful [146].

During the late 1970s it was recognized that beryllium would be the most efficient material for neutron monochromators, both because of its excellent nuclear properties and its excellent crystallographic properties [147, 148]. Many attempts to obtain beryllium single crystals with monochromator qualities failed [146, 149 – 152].

Crystals with a diameter of 15 mm having a proper substructure can be grown by crucibleless zone melting at a rate of 1 mm/min. The application of the necking technique is inevitable. A modified double-ellipsoid mirror furnace, originally developed for crystal growth experiments during spacelab missions, is used [153]. The mosaic spread of the as-grown beryllium crystals can be increased from a few minutes to any desired value by plastic deformation on prismatic planes [154].

7. Environmental Protection

Because of the toxicity of beryllium vapor and dust, all operations should be carried out in properly ventilated rooms, and with vented equipment. Source exhaust has been found to be most effective [155 – 157]. In the presence of poorly controlled high workplace concentrations, fine-dust masks with filters of the specific safety level must be worn. The following limits have been recommended by the U.S. Atomic Energy Commission and the American Conference of Governmental Industrial Hygienists as a guideline for controlling beryllium hazards:

1) In-plant atmospheric concentration should not exceed 2 $\mu g/m^3$ throughout an 8-h working day.

2) A brief exposure should not exceed 25 μg/m^3.
3) In the neighborhood of a plant handling beryllium the average monthly concentration should not exceed 0.01 μg/m^3.

In order to meet these safety regulations the plant exhaust air has to be efficiently filtered before it is discharged into the atmosphere. All persons employed in processing areas with high risk potential for beryllium dust exposure are advised to wear shop-laundered work clothes to prevent neighborhood contamination. Care must also be exercised in disposal of wastes from beryllium facilities: securely packed solid wastes are disposed by ground burial in concrete trenches. Liquid wastes are chemically treated to remove the toxic substances and to bring down the beryllium concentration to a safe level of approximately 1 ppm before discharge into public sewers.

In order to monitor the workplace concentration of 2 μg/m^3, dust collectors must have suction speeds between 0.02 and 2 m^3/min, depending on the type of sampling [155]. Presently a sufficiently sensitive analytical method for detecting the comparatively low beryllium concentrations is spectral analysis. Metallic beryllium in powder form can burn when ignited by sparks or an external heat source but does not self-ignite or explode. Beryllium oxide and alloys are not combustible. The naturally occurring isotope ^{9}Be is not radioactive.

8. Quality Specifications

To date there is only one company — Brush-Wellman Inc. — in the Western world that produces beryllium, beryllium-rich alloys, and beryllium compounds commercially. Brush-Wellman Inc. produces beryllium from bertrandite by the SX-Carbonate process, reduces beryllium fluoride with magnesium, and refines it by vacuum melting and casting. Different grades are produced by different powder-metallurgy processes and metallurgical treatments, e.g., forging, extruding, rolling, and annealing.

The composition, yield strength $\sigma_{0.2}$, tensile strength σ_F, and failure strain δ of several typical, commercial types of beryllium are compiled in Tables 5 and 6. However, these values guaranteed by the manufacturers are generally exceeded. The vacuum hot-pressed materials of Table 5 are used in nuclear technology, aeronautics, astronautics, and wherever high strength is required. The table shows that the yield strength and tensile strength increase with oxide content, while the elongation is not significantly affected. The brake grade (BG-170) is characterized by greatly reduced hot brittleness (Curve e in Fig. 3) [68, 69]. In the case of the instrument grades I-220A and I-400, the concentration of impurities is used to give a high precision elastic limit (PEL), below which the plastic strain is smaller than 10^{-6} or one microstrain.

Table 5. Manufacturer-guaranteed composition and mechanical properties of various grades of beryllium [158]

	S-65B	S-100E	S-200E	I-70A	I-220A	I-400	BG-170

Microyield, min. MPa	–	–	–	–	34	55	–

* BeO specified is minimum in this instance.

Table 6. Mechanical properties of various semifinished beryllium products [158, 159]

	Plates *	Extruded parts *	Forged parts *	Wire, Ø <0.25 mm
BeO content, wt% max.	2.0	2.0	2.0	0.02
$\sigma_{0.2}$, MPa	350	280	280	760
σ_F, MPa	480	480	450	900
δ, %	10	5	3	1

* Properties parallel to the direction of extrusion or to the rolling plane.

The development of texture in extruded parts and plates results in failure strain values of 5 and 10% in the direction of extrusion and in the rolling plane, respectively (Table 6); perpendicular to this direction the failure strain is < 1%. Forged parts have elongations of 3%, and high-strength wire (Ø < 0.25 mm) has an elongation of 1%.

As an example of the effect of temperature on tensile strength, yield strength, elongation, and necking at failure, the values measured for plate material parallel to the plane of the plate are plotted in Figure 5. The plate material was produced by cross-rolling high-purity isostatically hot-pressed ingot material.

Figure 5. Mechanical properties of high-purity beryllium [160]

The creep rupture strength is usually high [67, 161, 162]. In the case of cross-rolled plates the ten-hour creep rupture strength is equal to the tensile strength up to 800 K and can be significantly increased by carbon or beryllium oxide [37]. The little information that is available on the fatigue strength [161 – 165] (Fig. 6) indicates that beryllium has high fatigue strength and that the dynamic crack propagation is much less critical under alternating stress than under normal stress.

Figure 6. Fatigue strength of pressure-sintered, hot-worked beryllium [161]
a) Extruded and forged; b) Cross rolled

A compilation [163, 164] of the K_{Ic} (a measure of the toughness) values published so far shows that there is a great deal of variation. Most values lie between 10 and 20 MPa/m$^{1/2}$, but values up to 40 MPa/m$^{1/2}$ have been reported. However, the impact strength of notched and unnotched specimens is very low and depends on the type of working (Table 7).

Table 7. Impact strength (Charpy test), 10^{-2} MPa, of beryllium produced in various ways [58]

	Un-notched	Notched
Cast and extruded	0.16	–
Pressure sintered	1.1 – 3.4	0.68 – 1.3
Pressure sintered and extruded	5.6 – 6.1	–
Pressure sintered and rolled	2.7 – 4.1	–

The hardness of high-purity beryllium (Pechiney SR) is plotted in Figure 7 as a function of the mean grain size. The Brinell hardness of commercial pressure-sintered beryllium varies between 100 and 200, depending on the composition of the tested material [52].

Figure 7. Brinell and Rockwell hardnesses of high-purity beryllium (Pechiney SR) as a function of the mean grain size [74]

9. Beryllium Alloys

Beryllium-rich alloys have little industrial importance. The motivation for industrial research on beryllium alloys [10, p. 555], [12, p. 179], [15, pp. 601, 634], [17, p. 103], [132, 166 – 174] is not great because the solubility of most elements in solid beryllium is low ($\ll$ 1 mol%), and only copper, nickel, cobalt, iron, silver, and platinum have solubilities between 1 and 10 mol %, even at elevated temperatures. In addition, most metals form intermetallic compounds with beryllium [25, 77 – 79], and these intermetallics are usually quite brittle.

The only alloy containing large amounts of beryllium is Lockalloy [169], which is produced by powder metallurgy and contains 38 wt% Al. Aluminum does not form any beryllides. Therefore, this alloy contains beryllium grains embedded in the ductile aluminum phase with a more or less uniform distribution. This combination has a comparatively high modulus of elasticity (E), low density, and comparatively useful deformation behavior at room temperature. In addition, the notch sensitivity is lower than that of commercial beryllium (Table 8) [17, p. 103], [173]. However, Lockalloy has found only limited commercial use.

Composite materials made of beryllium and titanium have been developed for use, e.g., as compressor blades in gas turbines [174]. At present, these materials are the only composite materials that allow definite plastic deformation, are impact resistant, and offer the choice of secondary cold or hot working (Table 8). Furthermore they can be used to a limited extent even at 400 – 500 °C.

Beryllium is used as an alloying component in a number of age-hardening alloys [6] based on copper, nickel, cobalt, and/or iron [10, pp. 24, 49], [175 – 179]. Small amounts of beryllium improve the castability and oxidation resistance of aluminum and magnesium alloys [180 – 187]. These alloys are described under the principal component, → Copper Alloys, etc.

Table 8. Mechanical properties of powder-metallurgy Lockalloy [169] and beryllium – titanium composite materials (extruded powder mixtures) [174]

	ϱ, g/cm^3	σ_F, MPa	E, MPa	δ, %	$\sigma_{0.2}$, MPa
Lockalloy	2.09	386	200000	≈10	255
60 vol % Ti	3.4	1100	175000	5	≈770
40 vol % Ti	2.85	829	215000	2.5	≈580

10. Beryllium Compounds

Most beryllium compounds are important only in the production of beryllium metal, and these aspects are described earlier in this article.

Beryllium oxide [*1304-56-9*], BeO, M_r 25.0122, is obtained directly from beryllium hydroxide by calcination or from the basic carbonate, acetate, or sulfate by ignition [11]. The white, reactive powders differ in grain size, morphology, and impurity content [188]. They are used in the production of beryllium oxide ceramics, some of which have most unusual properties (Table 9). These ceramics are being used to an ever increasing extent [20].

Beryllium oxide is extremely stable [37]. However, its stability depends on its structure and is determined by the content of bound water. The higher the calcination temperature the more inert the beryllium oxide.

Beryl, see Chapter 5 and 6.

Bertrandite, see Chapter 5.

Beryllium nitride [*1304-54-7*], Be_3N_2, M_r 55.0440, is formed by heating beryllium in dry nitrogen in the presence of 2 – 6% hydrogen (700 – 1400 °C) or ammonia (1000 °C) [10, p. 570]. Moldings are produced by nitration of beryllium powder in porous molds by hot pressing the nitride at 1800 – 1900 °C. Relative densities up to almost 100% are achieved in this

way. Beryllium nitride is stable in dry oxygen up to 500 °C, but in the presence of water vapor it reacts at lower temperatures. Beryllium nitride is cubic at room temperature, converting to hexagonal at 1400 °C. Two other nitrides, $Be(N_3)_2$ and BeN, and two beryllium silicon nitrides, Be_4SiN_4 and $BeSiN_4$, are known. These ternary nitrides are very hard, extremely inert, and stable up to 1850 °C [191].

Table 9. Physical properties of beryllium oxide and carbide [7, 8], [10, p. 599], [11], [12, p. 267], [37, 189, 190]

	BeO	Be_2C

* Defined in Chapter 2.

Beryllium carbide [*506-66-1*], Be_2C, M_r 30.0355, ϱ 2.3 g/cm^3, *mp* ≈ 2400 °C, cubic, is obtained by direct reaction of solid or liquid beryllium with carbon or by reaction of beryllium oxide with finely divided carbon at 2080 °C [7], [10, p. 570]. Moldings are produced by hot pressing the carbide powder in graphite molds at 1800 – 1950 °C and 7 – 35 MPa. Beryllium carbide hydrolyzes very readily, even at room temperature, to form beryllium oxide and methane. At high temperatures it is not stable in air. Beryllium carbide vaporizes and decomposes in a vacuum above 2100 °C. The properties given in Table 10 are reference values because the beryllium carbide grades which were tested had indefinite structure. The nuclear properties of beryllium carbide are favorable. Beryllium borocarbide is extremely hard and is formed by melting mixtures of beryllium oxide, boron, and carbon in an electric arc.

Beryllium hydride [*7787-52-2*], BeH_2, M_r 11.028, is a very light (ϱ 0.58 g/cm^3), white powder at room temperature that is difficult to prepare. It dissociates into beryllium and hydrogen at ≈ 130 °C [37]. Beryllium hydride is of interest as a high-energy solid fuel.

Beryllium hydroxide [*13327-32-7*], $Be(OH)_2$, M_r 43.028, is obtained as a white voluminous precipitate on addition of bases to beryllium salt solutions. The fresh precipitate dissolves in sodium and potassium hydroxide and ammonium carbonate solution, but it ages quickly and becomes less and less soluble. The hydroxide also dissolves in aqueous $BeSO_4$ to form basic sulfates.

Basic beryllium carbonate, $BeCO_3 \cdot n\ Be(OH)_2$, $n = 2 – 5$, is formed in the reaction of beryllium salt solutions with alkali-metal or ammonium carbonate solutions. If excess ammonium carbonate is used, then a readily filtered precipitate of variable composition is formed on boiling. This salt is a suitable starting material for the preparation of beryllium salts of all types. Gentle calcining causes ammonia to escape, leaving beryllium oxide.

Beryllium nitrate, $Be(NO_3)_2 \cdot 4\ H_2O$, M_r 205.08, is obtained by dissolving pure hydroxide or gently calcined, pure basic carbonate in nitric acid and concentrating the solution until crystallization takes place. Concentrated solutions are also commercially available. The nitrate is sometimes used in the incandescent gas mantle industry for stiffening mantles.

Beryllium sulfate [*7787-56-6*], $BeSO_4 \cdot 4\ H_2O$, M_r 177.14, is obtained by heating beryllium oxide with sulfuric acid. The tetrahydrate crystallizes from the aqueous solution in well-developed crystals. It can be obtained in very pure form by this method. The tetrahydrate is stable in air, can be dehydrated at about 400 °C, and decomposes above 600 °C to sulfur trioxide. The aqueous solution can dissolve considerable quantities of BeO to form basic sulfate. The sulfate is important chiefly for the recovery of beryllium.

RT = room temperature.

Beryllium fluoride [*7787-49-7*], BeF_2, M_r 47.01, is a white, freely soluble, low-melting salt. Molten beryllium fluoride is a poor electrical conductor due to the its covalent character. (See Section 6.3 for production of BeF_2.) In addition to its use as an intermediate in the preparation of beryllium, it is also sometimes used as an additive to welding and soldering fluxes because it dissolves metal oxides readily.

Beryllium chloride [*7787-47-5*], $BeCl_2$, M_r 79.92, crystallizes in asbestos-like matted needles. It is extremely hygroscopic, forming a tetrahydrate. Its reaction with water is intensely exothermic and is accompanied by the release of HCl vapor. Beryllium chloride melts at 416 °C, boils at 520 °C, and, like the fluoride, is a poor electrical conductor in the molten state. (See Section 6.3 for production of $BeCl_2$.) Its principal uses are as the raw material for the electrolytic production of beryllium and as the starting material for syntheses of organoberyllium compounds.

Beryllium bromide, [*7787-46-4*], $BeBr_2$, M_r 168.85, melts at 490 °C. It is obtained as white needles by the reaction of bromine with a mixture of beryllium oxide and carbon. It is used in organic syntheses.

Beryllium orthophosphate, $Be_3(PO_4)_2 \cdot 6\ H_2O$, M_r 325.08, is obtained by reaction of beryllium salts with disodium phosphate or diammonium phosphate in acetic acid solution. Its solubility is very low at room temperature but increases sharply with temperature.

Beryllium ammonium phosphate, NH_4BePO_4, whose composition varies greatly due to partial separation of beryllium hydrogen phosphate, is sparingly soluble. Freshly precipitated NH_4BePO_4 is amorphous.

Aqueous *beryllium perchlorate* [*13597-95-0*], $Be(ClO_4)_2$, is a solvent for cellulose.

Basic beryllium acetate [*19049-40-2*], a hexaacetato complex, $Be_4O(CH_3COO)_6$, like the acetylacetonate and a few other organic beryllium compounds can be distilled without decomposition. Insoluble in water, it melts at 280 °C and boils at 331 °C. The organic beryllium compounds are being used to an increasing extent as intermediates in the purification of beryllium.

Beryllides of some transition metals are promising structural materials or protective coating materials for high-temperature applica-

tions because of their low density, high melting point, good mechanical properties, and resistance to oxidation, even up to high temperatures (Table 10) [192 – 197].

11. Chemical Analysis

The quantitative determination of beryllium, even in very small amounts, is especially important because of the toxicity of beryllium [155, 198]. The best method is atomic absorption spectrometry. When an acetylene/nitrous oxide flame is used, even beryllium oxide is excited, and it is possible to analyze any solution or dispersion without preliminary treatment [155, 199, 200]. Other methods [201 – 205] have also been described.

12. Storage, Transportation, Legal Aspects

Solid parts and structures made from beryllium metal, alloys, and ceramic beryllium can be stored and transported safely without special precautions as long as neither vapor nor dust is generated. Beryllium and beryllium oxide powder have to be handled with care, as is described in Chapter 7. For storage and transportation of the powders, sealed, unbreakable containers and proper instructions are a necessity.

Because beryllium is used mainly in military, nuclear, aeronautical, and rocket technologies, its trade is restricted. A special license is necessary for export from the United States.

13. Uses of the Metal

The properties of beryllium, especially the mechanical properties, are strongly affected by even small amounts of additives, e.g., 1000 ppm or less, and in this sense even commercial grades of beryllium (Table 5) represent alloys. The crucial advantage of beryllium over other materials is its combinations of favorable properties. Detailed discussions of the relationship between properties and uses have been published [19, 41].

The low density of beryllium combined with its high strength, high melting point, and resistance to oxidation is the basis for its use in structural parts that must be light and are exposed to inertial or centrifugal forces. In addition, it has a high modulus of elasticity, which gives light-weight components a high degree of rigidity [19]. Another area of use is in so-called dimensionally stable parts, in which high microyield strength and good thermal conductivity and reflexivity are exploited. It is an excellent heat sink, and therefore used especially for brake systems of airplanes. Applications in civilian nuclear reactors as reflectors and moderators have not met expectations because of radiation damage. However, its favorable nuclear properties have been exploited in weapons systems and in various physical instruments. Beryllium single crystals are the most efficient material for neutron monochromators. Beryllium foil is widely used as windows in energy-dispersive X-ray analyzers.

14. Economic Aspects

Data on production and consumption of beryllium is scanty and incomplete, in most cases because beryllium is used mainly for military and similar purposes. The most complete summary is published annually by the U.S. Bureau of Mines (Table 11), but the data mainly concerns mined beryl.

15. Toxicology and Occupational Health

Occupational Exposure. Exposure to beryllium and inorganic beryllium compounds (e.g., beryllium oxide, beryllium sulfate, beryllium fluoride) can lead to impairment of human health. The highest levels of human exposure occur through occupational inhalation of beryllium dusts or fumes. But also dermal contact with beryllium-containing products is a possible exposure pathway. The general population can be exposed to trace amounts of beryllium through inhalation of air, consumption of food and water, and skin contact with air, water, or soil that contains beryllium. The inhalation route is of greatest concern for systemic effects. Beryllium and its compounds are poorly absorbed after oral (<

Table 11. World production of beryl, as compiled by the U.S. Bureau of Mines, in short tons (2000 pounds)

1%) and dermal exposure. The respiratory tract is the primary target of beryllium toxicity [206]. Workers with the highest potential for exposure include beryllium miners, beryllium alloy makers and fabricators, phosphorus manufacturers, ceramics workers, missile technicians, nuclear reactor workers, electric and electronic equipment workers, and jewelers [207]. About 134 000 workers are potentially exposed to beryllium and its compounds in the USA [208].

Toxicokinetics and Metabolism. After inhalative exposure beryllium and its inorganic compounds are absorbed primarily in the respiratory tract. The absorption of inhaled beryllium depends on physical and chemical properties like particle size and solubility of the beryllium compounds. The higher the solubility, the faster relatively uniform distribution in the organism takes place, with moderate retention in the lungs [209]. In the case of poorly soluble beryllium compounds, 70 – 99% remains in the lungs [210]. Clearance from the lung is biphasic; the initial phase is rapid and involves mucociliary clearance, while the second, slower phase involves translocation to tracheobronchial lymph nodes, alveolar macrophage clearance, and solubilization. In humans beryllium often is detectable in the lungs for several years and can also serve as evidence of previous exposure. Beryllium is poorly absorbed from the gastrointestinal tract. Dermal absorption from intact skin is also low. Absorbed beryllium is distributed throughout the body via blood. Beryllium was detected in lungs, brain, kidney, spleen, liver, muscle, heart, and skeleton. There is suggestive evidence that beryllium is transferred across the placenta and excreted via breast milk. The primary routes of elimination are urine and feces. Beryllium and its inorganic compounds are not metabolized in the body. Only soluble beryllium salts are partially converted in the lungs into less soluble forms [206].

Mechanism of Action. Beryllium can elicit a strong cellular immune response in vivo. Chronic beryllium disease is an allergic reaction of the delayed type, in which beryllium appears to act as a hapten that binds to peptides on mucosal surfaces. In susceptible individuals the beryllium-peptide complex initiates an immune response which may progress ultimately to granuloma formation in the pulmonary interstitium. The genotoxic effects of beryllium are based on the induction of DNA-protein complexes [211]. Beryllium may inhibit the repair of DNA damage and act in a cooperative manner to enhance the genotoxicity of other agents. The effects of beryllium on cellular metabolism and DNA replication combined with its ability to promote an immune response with concomitant induction of reactive oxygen species (and oxidative DNA damage to the target tissue) may be sufficient to promote carcinogenesis in vivo [212]. Beryllium is the least studied carcinogenic metal with respect to gene modulation.

The mechanisms by which beryllium induces tumors are still obscure [213].

Effects in Humans. The main adverse health effects of beryllium are respiratory effects and lung cancer following inhalative exposure, gastrointestinal effects following oral exposure, and skin effects following dermal exposure.

Respiratory Effects. The inhalation of beryllium can cause, depending on duration and level of exposure, acute or chronic beryllium disease (berylliosis). Acute beryllium disease is usually observed after inhalative exposure to high beryllium concentrations ($> 100\ \mu g/m^3$). It is the result of the direct toxicity of water-soluble beryllium compounds. Acute beryllium disease has a short induction period and is usually resolved within a couple of months after termination of exposure. It is believed to be an inflammatory response to beryllium, and most regions of the respiratory tract are affected. Individuals who have previously suffered from acute beryllium disease have an elevated risk of lung cancer. Long-term exposure to relatively low beryllium concentrations ($\geq 0.5\ \mu g/m^3$) of soluble or insoluble beryllium compounds can result in chronic beryllium disease. The duration of this disease is more than one year, and the latency period may range from a few weeks to 20 years after exposure. Here immunological mechanisms in the sense of an allergic reaction of delayed type play a role.

Dermal Effects. Edematous papulovesicular dermatitis was observed in workers exposed to airborne beryllium compounds. Beryllium exposure may also cause a delayed hypersensitivity reaction in the skin. Skin granulomas from beryllium workers contained the same mononuclear infiltrates as detected in the lungs [206].

Cardiovascular Effects. Severe cases of chronic beryllium disease can result in cor pulmonale, that is, hypertrophy of the right heart ventricle. It is not likely that the cardiac effects are due to direct toxicity to the heart, but rather are a response to impaired lung function.

Renal Effects. Kidney stones were observed in association with chronic beryllium disease [206].

Immunological and Lymphoreticular Effects. While acute beryllium disease is a chemical pneumonitis, chronic beryllium disease appears to be an immunological disease. Beryllium can induce cell-mediated immune responses. Beryllium-sensitized cells accumulate at sites of chronic beryllium disease, resulting in granulomas in the lungs. Nonspecific immunological findings in chronic beryllium disease include an increase in serum gamma globulin levels. The existence of specific antibodies to beryllium was reported.

Genotoxicity. Beryllium compounds yielded contradictory results in mutation or chromosomal aberration assays. Bacterial tests were largely negative; mammalian test systems showed evidence of beryllium-induced mutations, chromosomal aberrations, and cell transformation. No genotoxic effects (micronuclei and sister chromatid exchange) were observed in a group of beryl cutters. Thus, the results of genotoxicity assays of soluble beryllium compounds are inconsistent. Differences in the results depend on assay conditions, type of assay, and chemical form of beryllium. Soluble beryllium compounds appear to be weakly genotoxic. The carcinogenicity of beryllium is supported by the mutagenic potential in some of these studies [206, 214, 215].

Reproductive and Developmental Effects. The available data on the potential of beryllium to induce reproductive and/or developmental effects are inconclusive [206].

Carcinogenicity. Increased mortality from lung cancer was found in epidemiological studies of workers in beryllium plants [216 – 221] and in an evaluation of the American Beryllium Case Register [222, 223]. A relationship between the duration of employment and lung cancer mortality was not determined. However, there was an association between death from lung cancer and an increasing time span since the beginning of employment or previous acute beryllium disease. Exposure to high levels of beryllium, which is regarded as the trigger for acute beryllium disease, is associated with a significantly increased risk of lung cancer [224, 225]. The data indicate that the carcinogenic effects occur mainly at high beryllium concentrations, which are no longer to be expected in workplaces today. The epidemiological data for the pulmonary carcinogenicity of beryllium and its inorganic compounds is also supported by the results of animal experiments [210].

Occupational Health (Clinical Symptoms, Diagnosis, Treatment and Prevention).

Acute Beryllium Disease. Acute beryllium disease develops after a short and heavy exposure. Because such high beryllium concentrations are no longer to be expected in workplaces today, this form of the disease is rarely encountered today, except for accidental or unexpected exposure. Acute beryllium disease usually lasts for less than one year, has a latency period of usually around three days, and may take several forms. Symptoms are coughing, breathing difficulties, tightness of the chest, appetite and weight loss, and general weakness and tiredness. Pneumonitis is the most serious of the acute effects from beryllium exposure. It varies in severity and can result in death as a result of the formation of severe pulmonary edema. But fatal cases are rare and recovery is usually complete in about six months. In isolated cases transition to the chronic form is possible without further exposure and after several years [211]. Diagnosis and evaluation of acute beryllium disease requires the identification of the exposure conditions and the analysis of the employment history. Treatment for acute beryllium disease includes removal from exposure, bed rest, and administration of oxygen and corticosteroids, which prevent inflammation.

Chronic Beryllium Disease (Berylliosis). Unlike the acute form, chronic beryllium disease is still frequent in exposed and susceptible individuals. This disease is caused by an immune reaction to inhaled beryllium that is deposited in lung airspaces and retained for a prolonged period. This disease primarily affects the lungs, but it may also affect other organs because the blood transports beryllium throughout the body. Observed symptoms were weight loss, dyspnea, cough, fever, chest pain, cor pulmonale, fatigue, and appetite loss.

On physical examination, signs of chronic beryllium disease are rales (changes in lung sounds), cyanosis (lack of oxygen), digital clubbing, and lymphadenopathy (enlarged lymph nodes). An X-ray of the lungs may show many small scars. Patients may also have an abnormal lung function. Histological examination of the lung tissue after biopsy may show granulomas, which are signs of damage due to the body's reaction to beryllium. Chronic beryllium disease may be confused with other lung diseases, especially sarcoidosis. A blood test, the beryllium-induced lymphocyte proliferation test (Be-LPT), is a valid method for detecting beryllium sensitization, but it is not sufficient for diagnosis of chronic beryllium disease. The presence of granulomas in the lung of an individual with a positive lung Be-LPT confirms the presence of chronic beryllium disease. In the absence of granulomas or other clinical evidence, individuals with a positive Be-LPT are classified as sensitized to beryllium. In beryllium workers involved in the production of beryllia ceramics and nuclear weapons, sensitization rates of 1 – 15% were found [206]. In more than half of the beryllium-sensitized workers chronic beryllium disease was diagnosed.

The only available therapy for chronic beryllium disease is the administration of corticosteroids. Individuals with impaired respiratory gas exchange may require continuous oxygen administration. Asymptomatic individuals who are only sensitized do not need medical treatment. But once sensitization has occurred, it is medically necessary to prevent additional exposure to beryllium.

Because high beryllium concentrations trigger the occurrence of acute beryllium disease, which is a risk factor for lung cancer, the aim of prevention must be to minimize and control exposure at the workplace. Enclosed processes separate workers from harmful substances and prevent toxic substances from escaping into the workroom. Workers should use wet processes or pellets instead of powders. Workplaces need warning devices in areas with a potential of massive contamination. Air from the local exhaust system should be conducted to the atmosphere through high-efficiency filtration equipment. Good housekeeping includes proper storage of substances, frequent disposal of waste, prompt spill cleanup, periodic maintenance of equipment, and no dry sweeping. Respiratory protective devices and protective clothing can help reduce exposure. The workplace should also provide training and educational programs to inform workers about the nature of substances they are exposed to and how to work safely.

Medical surveillance should include chest X-rays and spirometry prior to employment, annually, and on termination. For minimum exposure risks, less frequent intervals may be sat-

isfactory. A possible sensitization to beryllium may be tested by Be-LPT.

Regulations. The OSHA PEL and the ACGIH TLV-TWA for beryllium are 2 μg/m^3. The OSHA ceiling concentration is 5 μg/m^3, and the ACGIH TLV-STEL is 10 μg/m^3. The National Toxicology Program (NTP) lists beryllium and certain beryllium compounds as human carcinogens. The IARC has classified beryllium and beryllium compounds in Group 1, carcinogenic to humans [226]. In Germany, beryllium and its inorganic compounds are considered as human carcinogens and classified in carcinogenicity category 1 by DFG Commission for the Investigation of the Health Hazards of Chemical Compounds in the Work Area [210]. In contrast, the EPA concluded that the human data only provide limited evidence and classified inhaled beryllium in Group B1, a probable human carcinogen [206].

1. Introduction

A *beverage* is defined as a liquid for drinking, and includes the following general categories:

1) water (natural, mineral, carbonated, non-carbonated);
2) fruit and vegetable juices (single-strength, concentrated), and their modifications (drinks, comminuted, nectars, fortified, carbonated);
3) soft drinks (carbonated, non-carbonated, packaged, diet);
4) tea;

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a04_035

5) coffee;
6) milk;
7) beer;
8) wine (still, carbonated, dry, sweet);
9) distilled spirits.

Beverages can be further differentiated into nonalcoholic and alcoholic types; in general, a *nonalcoholic beverage* may be fermented or unfermented but must contain less than 0.5 vol% ethanol. Differentiation is best exemplified by the malt beverages. "Beer" (alcoholic beverage) is defined as beer, ale, porter, stout, or other similar fermented beverages containing 0.5 vol% or more ethanol. The product must be brewed or produced wholly or in part from malt. On the other hand, a "cereal beverage" (nonalcoholic beverage) is defined as a fermented or unfermented malt beverage containing less than 0.5 vol% ethanol [1]. Details on regulatory control of standards and of the various phases of production, labeling, and advertisement of alcoholic beverages are found in Title 27 of the United States Code of Federal Regulations [1]. This article covers only nonalcoholic beverages and, specifically, those beverages confined to categories (1), (2), and (3).

1.1. Drinking Water

Water [*7732-18-5*] for drinking contains no pathogenic organisms, has a pH between 6.5 and 8.0, contains minor amounts of organic matter, and may or may not contain mineral salts. The maximum levels of allowable constituents in drinking water are: 1000 ppm total solids, 250 ppm Cl, 250 ppm SO_4, 100 ppm Mg, 0.5 ppm Zn, 0.3 ppm Fe, 0.2 ppm Cu, and 0.1 ppm Pb [2]. Drinking water containing no mineral salts is classified as:

1) *Demineralized:* manufactured by passage of natural water through an ion-exchange medium.
2) *Distilled:* natural water is vaporized and subsequently condensed leaving behind nonvolatile minerals.

1.2. Fruit and Vegetable Juices and Derived Juice Products

The expression or pressing of a fruit or vegetable yields a product which contains not only a liquid component (water, soluble solids) but, most often, an insoluble component (finely suspended colloidal particles). Generally, insoluble components are removed commercially by a finishing process, but they may be deliberately added to certain juices (apple, citrus) to mimic fresh juice and/or as an economic matter to increase juice yield. United States Standards of Identity explicitly define processing and compositional variable limits for most juice products.

Fruit. A *fruit juice* is the unfermented, undiluted, extractable fluid content resulting from expression of fruit. *Fruit drink* or *diluted fruit beverage* are descriptive phrases used to define a non-carbonated beverage containing > 0 % but < 100 % fruit juice. A diluted fruit juice beverage may contain added water, sugar, other sweeteners, gum arabic, artificial colors, flavors, vitamins, and acids (citric, malic, fumaric). The percent of fruit juice(s) in a diluted juice beverage is calculated on the basis of the soluble-solids content of the undiluted (single-strength) juice and is declared on a vol% basis. In diluted juice beverages containing only one type of fruit juice, the U.S. Food and Drug Administration [3] has proposed a rule that would require a label statement declaring the percent of juice in 5 % increments. Beverages containing > 0 % but < 5 % would be declared as "less than 5 %". Beverages containing multiple juices (e.g., fruit punches) may declare the percentage of the total juice content or a statement of the percentage of each juice represented.

Some fruit juices are too acidic, too strongly flavored, or too bland to yield a natural, pleasant-tasting beverage. However, delicious drinks may be prepared from these fruits by addition of flavor-modifying ingredients and by dilution with a thin syrup. Also, the delicate flavor of many fruit beverages is enhanced if fruit solids are added. The solids are converted to a soft, smooth pulp which enhances flavor and imparts a desirable mouth-feel. Therefore, a *fruit nectar* is a pulpy fruit juice to which may be added sugar syrup, acids, vitamins, pectin, essences, and water. Sweeteners include sugar, invert sugar syrup,

dried corn syrup, glucose syrup, and dried glucose syrup; optional ingredients include lemon juice; citric, malic, and fumaric acid as acidifiers; and ascorbic acid as an antioxidant and as a vitamin. A typical nectar, e.g., pear, contains water, pear pulp and juice, corn sweetener, sugar, citric acid, and ascorbic acid (vitamin C). Most nectars contain $\geqq 50$ % pure juice, but for purposes of identity, they cannot be classified as a fruit juice because of added ingredients.

Vegetable. *Vegetables* may be grouped into 5 general types based on the part which is consumed and, hence, on the part that is most often used to derive a juice product:

1) Leaf or stem vegetables, e.g., celery, cabbage, rhubarb
2) Root vegetables, e.g., carrot, beet, turnip
3) Fruiting vegetables, e.g., tomato, cucumber, eggplant, pepper
4) Immature flower bud vegetables, e.g., cauliflower, broccoli, artichoke
5) Legumes, e.g., pea, bean, soybean

The major constituent of all vegetables is water; the percentage ranges from about 70 % (legumes) to about 95 % (roots, leaves, stems). Vegetable juices cannot satisfy all of the daily nutrient requirements of human diets, but they are an important contributor of vitamins and minerals to that diet.

The *juices* derived from vegetables are generally grouped into 6 classes [4]:

1) Juices prepared from normally acid vegetables, e.g., tomato and rhubarb; may be processed at low temperature.
2) Vegetable juices or their blends acidified with highly acid products, such as tomato, sauerkraut, or rhubarb juice; tomato juice is often a primary ingredient.
3) Vegetable juices acidified with organic or mineral acids can be processed at relatively low temperature.
4) Excess juices derived from fermented vegetables are either used in their natural state or heat processed at low temperatures, e.g., sauerkraut juice.
5) Vegetable juices or their blends which are not acidified must be processed in a retort at high temperature.
6) Juices freshly extracted from nonacid vegetables must be consumed quickly (specialty or health food stores); these juices are neither heat-stabilized nor acidified.

1.3. Carbonated and Non-carbonated Beverages

Carbonated and non-carbonated beverages, more commonly known as soft drinks, represent a very broad category that overlaps, to some extent, the category of fruit and vegetable juices and their modified products. A fine distinction cannot be made because the two beverage types contain natural product ingredients (in whole or part). A *soft drink* is defined as a nonalcoholic beverage of many flavors [2], and includes: (1) any fruit drink (synthetic or natural), squash, crush, or cordial; (2) soda water, Indian or quinine tonic water, and any sweetened, artificially carbonated water; (3) ginger beer and any herbal or botanical beverage. Soft drinks are also called carbonated beverages, soda water, soda, cola, pop, or drinks.

Carbonated. Carbonation is a term used to identify the dissolution of carbon dioxide gas in water utilizing pressure and temperature. The dissolved gas not only imparts a distinctive taste, zest, and sparkle to the beverage, but the dissolved gas also plays a major part in inhibiting or destroying harmful bacteria [5]. Soft drink beverages contain carbonation ranging from 1 to 5 volumes of gas (1.05 to 5.27 kg/cm^2 gas pressure) per volume of liquid; there is no standard volume of carbonation for the various type soft drinks. Soft drink classification based on the degree of carbonation has been defined as [6]: 3.5 or more CO_2 volumes (ginger ale, colas, tonics, club soda), 2.5 – 3.5 CO_2 volumes (root beer, lemon, lime, cream soda, grapefruit), and 1.0 – 2.5 CO_2 volumes (strawberry, cherry, grape, orange, pineapple, punch).

There are virtually hundreds of carbonated soft drink beverages on the market with scores of natural and synthetic flavors. The ingredients of a typical carbonated soft drink include: purified water that has been saturated with CO_2 gas, sweetening agents (dry or liquid sugars, non-nutritive sweeteners), acids (acetic, cit-

ric, fumaric, gluconic, tartaric, phosphoric), flavors (derived from fruit, vegetables, bark, roots, leaves, or artificial flavors), color (natural or artificial), preservatives, and other optional ingredients (e.g., vitamin C).

Non-carbonated. A non-carbonated, nonalcoholic beverage cannot be sharply defined. Simply stated, commercially-made and natural (coffee, tea, bottled water) non-carbonated beverages are those which do not contain pressurized carbon dioxide. In contrast to soft drinks, non-carbonated beverages contain components derived from natural fruit, vegetable, meat, or dairy products. The most popular of the non-carbonated types are the fruit beverages; these are found under a variety of names – fruit drinks, juice drinks, breakfast drinks, punches, ades, treats, etc. Modifications of non-carbonated fruit beverages include the electrolyte drinks – Gatorade, Sunshine Orange Thirst Quencher [7], fortified drinks (mostly with vitamin C), and protein-enriched drinks (protein-enriched citrus juices, fruit-milk beverages). In addition to the fruit beverages, there are non-carbonated beverages of the broth type (clam, meat), vegetable (vegetable juice cocktails, vitamin fortified), and dairy (chocolate drinks).

2. Mineral Water

History [8–11]. Water is an essential element of life and health. Although humans could survive for more than 30 d without eating, they would die of thirst after 8 – 10 d without drinking.

The first civilizations grouped around sources of water, and considerable engineering efforts were spent on the construction of aqueducts, e.g., by the Romans. Since ancient times, famous mineral springs were praised, e.g., by Homer or Pindar. The healing power of the sulfur springs of Thessalia was mentioned by Aristotle. Hannibal sent his soldiers to the Pyrenees, where they recovered at the mineral spring of "Perrier", which rises at Vergèze in Southern France. The legionaries of Caesar cured themselves at the springs of Plombières and Vichy, where the first medical facilities were installed.

Pliny the Elder was the first to classify mineral waters according to their *nature* (hot, warm, cold, sulfurous, aluminous, nitrous, bituminous, ferrous, and carbonated), and according to their *therapeutic effect* (purgative, purifying, stomachic, digestive, fortifying, recalcifying, reconstituent), or their efficiency against gout, sciatica, fractures, dislocations, injuries, fever, gallstones, or infections of the throat, ears, skin, or eyes.

Mineral waters were administered in the same way then as today, i.e., by drink, inhalation, bath, shower, sauna, etc.

The fall of the Roman Empire was accompanied by a decline in the use of mineral springs. This trend was not reversed until the 16th century. In 1605, Henry IV installed the "Superintendent General of Spas and Mineral Springs of the Kingdom." In the same year, one of the first treatises on modern hydrology appeared: *"De l'usage et l'employ des eaux naturelles contre les maladies"* (On the use and application of natural waters against diseases) by Jean Ban.

2.1. Definitions of Mineral Water

2.1.1. European

This definition appears in the European Economic Community (EEC) guideline 80/777 of July 15, 1980 [12].

1) *Natural mineral water* is water free of harmful bacteria, originating from a subterraneous layer, and emanating from a source exploited by one or more natural or drilled outlets. Natural mineral water is clearly distinguished from ordinary drinking water by (a) its contents of minerals, trace elements, or other constituents, and sometimes by certain therapeutic effects; (b) its original purity. These characteristics are preserved because the water is underground and therefore sheltered from pollution.

2) These characteristics, which by nature give the natural mineral water properties beneficial to health, must be evaluated on the following levels: (a) geological and hydrogeological, (b) physical, chemical, and physicochemical, (c) microbiological, and (d) if necessary, pharmacological, physiological, and clinical.

(a) Geological and hydrogeological regulations require:

- exact location of recovery, i.e., the altitude and the topographical level, on a scale of 1 : 1000 or greater;
- detailed geological report on the origin and nature of the ground;
- description of the hydrogeological layer;
- description of the recovery operations;
- determination of the zone or of other measures for protecting the source from pollution.

(b) For physical-chemical and physicochemical regulations, the following must be determined:

- output of the source;
- temperature of the water at the outlet and the ambient temperature;
- relations existing between the nature of the ground and the type of mineralization;
- dry residues at 180 – 260 °C;
- conductivity at the given temperature;
- pH value;
- anions and cations;
- nonionized elements;
- trace elements;
- radioactivity at the outlet;
- if applicable, the relative proportions of isotopes of the constituent elements of water: oxygen (^{16}O, ^{18}O) and hydrogen (^{1}H protium, ^{2}H deuterium, ^{3}H tritium);
- toxicity of certain constituents of the water, taking account of limits fixed for each constituent.

(c) The microbiological regulations for the outline concern particularly:

- demonstration that parasites and pathogenic microorganisms are absent;
- the quantitative determination of revivable microorganisms as indicated by fecal contamination. The absence of the following microorganisms must be demonstrated: *Escherichia coli* and other coli strains in 250 mL at 37 °C and 44.5 °C; fecal streptococci in 250 mL; sulfite-reducing aerobic spores in 50 mL; *Pseudomonas aeruginosa* in 250 mL;
- the determination of the total content of revivable microorganisms per milliliter of water.

(d) The water must be subjected to clinical and pharmacological tests, following recognized scientific methods. According to the relevant regulations, the nature of the tests must be adapted to the natural mineral waters' own characteristics and to their effects on the human organism, such as diuresis, effects on gastric or intestinal functions, and compensation for mineral deficiency.

The characteristics of the water must be determined according to scientific methods approved by the authority responsible. The tests specified under (b) – (d) can be voluntary when the water shows characteristics of composition conforming to those of a water considered as a natural mineral water in the member state of origin before application of the present directive started. This is particularly the case when the water contains, at the origin and after bottling, more than 1000 mg of total solids or more than 250 mg of free carbon dioxide.

2.1.2. French

The term mineral water is reserved exclusively for spring water from deep, protected sources or from drilled sources subject to authorization and control by the mining office (Ministry of Industry) and whose exploitation is authorized by the Minister of Health after its therapeutic properties have been recognized by the Academy of Medicine (see also [13]).

As a result of the particular regulation applied, mineral waters are not required to conform to the norms defined for drinking water with respect to content of mineral salts or total hardness.

Mineral waters are compared neither to food (as drinking water), nor to dietetic products, nor to medicaments.

Normally, the harmlessness of mineral water is guaranteed by compulsory authorization for bottling (decree of 1964), which is only granted for waters whose sale poses no danger for the consumer.

All possible precautions must be taken to preserve all physiological, bacteriological, and pharmacological qualities of the water after recovery.

Nevertheless, mineral waters are very diverse in composition and effects. They can be either still or carbonated. In the latter case, the quantity of gas in the bottle is the same as the orig-

inal content from the source. These waters are termed "natural carbonated mineral waters" and are symbolized by "Perrier".

Two classifications for still waters have been adopted:

1) Classification according to *composition,* which is based on chemical content rather than on therapeutic criteria. Thus distinction is made between waters weakly or very weakly mineralized and those rich in mineral salts, those that are bicarbonated, sulfated, chlorinated, fluorinated, or rich in calcium, magnesium, or sodium.
2) Classification according to *therapeutic effects,* based on therapeutic properties: diuretics, laxatives; treatment of rheumatism, arthritis, lithiasis, diabetes, obesity, gout, high cholesterol levels, and ailments of the kidney, cardiovascular system, liver, stomach, and intestines.

2.1.3. Codex Alimentarius

Control of mineral waters by the Codex Alimentarius is under development. Initial studies retain certain elements of the European definition, but they do not appear to mention the properties beneficial to health, which appears to be a fundamental omission.

Of the three definitions discussed in this section, the French legislation appears to be the best because of its precise wording (see Section 2.3), and because its has benefited from long experience. Authorization for production of mineral water in France can only be granted after complete hydrogeological, chemical, and bacteriological studies lasting several years, carried out under the supervision of the ministries of agriculture, industry, and health, together with active participation of the Academy of Medicine and of the Superior Council of Hygiene.

The European legislation is precise in its definition but does not mention the authority which grants the authorization, nor the methods accepted. It systematically classifies highly mineralized water (more than 1000 mg/L) as mineral water. As for the Codex, this includes more or less everything from mineral water to simple source waters.

In the United States water is only designated as natural mineral water if it contains more than 500 mg/L of dissolved minerals.

2.2. Development of Mineral Water

Thermal Springs and Bottling. Over the centuries, consumption of mineral water was primarily the privilege of inhabitants and clientele of thermal springs. In the last decade, this empiricism has given way to methodological application of thermal therapy, which has become the subject of regular instruction in French medical faculties. Many of the doctors specialize in natural medication. They have succeeded in developing appropriate thermal cures for various illnesses. In France more than 500000 persons are treated each year at the thermal springs. Details of treatment and different techniques used can be found in [8–11], [14–19].

After 1918 mineral waters became increasingly available to the average consumer. Improved packaging methods coupled with increasing demand permitted large-scale commercialization. Patients at the thermal springs could benefit from these waters all year and could prolong the effects of their cure. It also resulted in new clientele concerned about health.

The need for a pure product resulted from "quality defects" of public water, which is initially impure and requires numerous treatment stages. Even if such treatment eliminates bacterial pollution, it still leaves traces of chlorine, which on one hand is considered by some to be carcinogenic and on the other hand gives the water a particularly unpleasant taste.

Also, the market for bottled mineral waters, which was only some 0.35×10^9 L in 1948, represented more than 10×10^9 L in Europe and the West in 1983. France sold more than 3.25×10^9 L, the Federal Republic of Germany ca. 2.6×10^9 L, and Italy 1.7×10^9 L. In terms of per capita consumption, France leads with more than 56 L/a, followed by Belgium (54 L/a) and the Federal Republic of Germany (46 L/a).

As a consequence of this considerable commercial expansion in Europe, the demand for local or imported mineral water increased all over the world. The most striking illustration of such an evolution is provided by the worldwide distribution of Perrier, a naturally carbonated mineral

water, covering the markets not only of Europe, but also of the United States, Japan, Australia, etc.

2.3. Legislation [12], [20], [21]

As a consequence of the growing popularity of bottled water, the French legislature formulated the decrees of April 30, 1930, March 28, 1957, and August 1, 1961; the decisions of August 1, 1961, and December 21, 1964; and the circular of July 23, 1957. These general texts, briefly summarized herein, effectively control French mineral water. Authorization for mineral water is granted to natural sources by the Academy of Medicine after examination of the dossiers from the Mining Office, the Superior Council of Hygiene, etc. The dossiers consist of: (1) geological studies and recovery work; (2) physiological and bacteriological analysis of the water; and (3) pharmacological, physicological, and clinical tests.

The water is subject to numerous controls at the outlet, in the thermal installations, during bottling, and during commercialization. These controls are carried out by the official laboratories, approved by the decrees of August 10, 1961, and December 21, 1964, and repeated by the directive of the EEC [12].

Bottling is subject to authorization; the criteria defining the norms of bottling are defined by all the existing regulations, including the draft regulations of the Codex Alimentarius and the French regulations [20] (Regulations 57404 of March 28, 1957 and 641255 of December 11, 1964; decisions of August 10, 1961 and December 21, 1964; circulars of July 23, 1957, October 24, 1960, and January 27, 1965), and the German draft regulations (DBMJFG 416/415 6411-I of February, 1983, draft regulations on natural mineral, spring water, and table water; Mineral- and Tafelwasser Verordnung), which retain the main points of the European directive 60/777 [12].

Certain regulations, such as the Codex, the German regulations, and even the European directive, tend to limit various minerals present in mineral water. This is contrary to the French concept of mineral water, which is that certain ions, in quantities much above those recommended for public water, are responsible for the beneficial effects.

2.4. Packaging of Mineral Water [22]

Mineral water must be bottled at the outlet, and can in no way be processed. Some companies have been granted special authorization to remove iron from their water to eliminate precipitation of brown ferric oxide. This can only be done if other mineral components are not affected. Some companies are allowed to reincorporate carbon dioxide if technical procedures require separation of this gas from the water before bottling. The percentage of carbon dioxide in the bottled water must be the same as in the original source water. In fact, if this water is transported long distances, a constant gas percentage identical to the original cannot be maintained, especially when the amount of gas is high.

Reincorporation of carbon dioxide generally involves collecting the gas at the fountainhead, storing it at high pressure in a tank, and eventually mixing the gas with the water during bottling.

Transportation of the water through a pipeline to a bottling plant close to the fountainhead requires a ministerial license with approval from the Academy of Medicine.

Containers must be transparent (apart from those intended for special markets, such as the airline companies, which demand cans). The maximum capacity of containers for retail sale must not exceed 2 L. Use of barrels and tanks is prohibited. Until 1968, glass bottles were the only authorized containers. Now packaging has been revolutionized with development mainly of poly(vinyl chloride) bottles. The plastic bottles must be manufactured in the bottling factory. Those used for plain and low carbonated mineral water are subject to government approval [20]. The plastic bottle must be tested separately with each mineral water to make certain that all constituent materials are inert and will not affect the properties and features of the water.

The tests, lasting at least three months, are effected by the National Health Laboratory in Paris. One of the main points is detection of vinyl chloride monomer (VCM) (European Directive of January 30, 1978). Up to now, no VCM has ever been detected in mineral water, the minimum detectable quantity being 0.002 ppm [23].

2.5. Regulations for Labeling

Labeling regulations are very precise. However, because there is no significant difference between the various sets of regulations, only the European directive of December 18, 1978 will be mentioned. This Directive specifies that any label, package, or advertisement must in no way be likely to delude the consumer. It also mentions the type of information that must be available to the consumer: (1) name of the product on sale, i.e., natural mineral water (a brand name, a trademark, or fictitious name cannot serve as a substitute), together with the name of the source and of the bottling site; (2) ingredients; (3) net volume.

2.6. Bottling

During the last few years, bottling methods have become increasingly more efficient because of the ever growing use of disposable (nonrefillable) bottles. In modern factories, these bottles represent 90 % of the production. The production rate on highly automated bottling lines is about 30000 to 50000 bottles an hour. Bottling lines using plastic bottles are called "integrated" lines, because these bottles are manufactured on site. Mineral water companies working with glass bottles are dependent on supply from external bottle manufacturers. The Perrier Co. is an exception to this rule. It has integrated a glass bottle factory with its bottling unit. This company now controls all stages of manufacturing.

2.7. Conclusions

Mineral waters are of considerable interest and are often misunderstood.

Health Interest. Millions of patients are received annually at thermal springs; vast quantities ($> 10^9$ L) of mineral waters are consumed annually.

Economic Aspects. An industry, directly or indirectly employing millions of people, has been created to satisfy the demand for mineral water by consumers, increasingly aware of their beneficial effects.

3. Fruit and Vegetable Juice Products

3.1. Temperate Fruits

Temperate fruits are grown on almost every continent, from the cool northern and southern temperate zones to the warm equatorial tropics where sufficient altitude permits growth. These fruits enhance the diets of millions upon millions of people by providing nutrients, diversification of diet, good taste, and eating enjoyment. The major temperate fruits covered in this section are apples, apricots, cherries, grapes, peaches, pears, and plums. World production figures of these temperate fruits in selected countries are shown in Table 1. Apples and grapes are the two principal temperate fruits.

The Federal Republic of Germany, Italy, and France are all major European *apple* producers. Even countries that are not major contributors to world apple production, such as Switzerland, find apples to be the most important fruit for fruit juice processing. The United States is the largest apple producer. Washington is the leading state with New York second. European apple crops show large variation in production so that in years of excess, apples normally used for the fresh market are processed into juice. In years of short supply, apples are imported from the United States and elsewhere.

Grapes have been cultivated for more than 5000 years. They are the largest in volume of any temperate fruit. Of the grapes grown in Europe, about 85 % are for wine, 15 % for fresh market, and only a negligible amount for grape juice or other products [27]. The United States produced 5.9×10^6 t in 1982. Of this California produced almost 93 %. The California grape crop was utilized as 12.7 % fresh, 28.5 % dried, and 58.2 % wine. Grape juice is processed from grapes grown in Washington, New York, and Michigan, with 44.5 %, 24.7 %, and 15.3 %, respectively, of the 316×10^3 t utilized for United States grape juice production [24], [25].

Apples are used as the example temperate fruit in this section because of their economic prominence and the wealth of scientific information on all phases of apple production and processing. Although grapes are the largest fruit

Table 1. Percentage of 1982 world production by select countries of major temperate fruits – 1982 [24–26]

	Apples	Apricots	Cherries	Grapes	Pears	Peaches and nectarines	Prunes and plums
Austria	1.7	2.5	2.5	1.0	1.1	0.3	0.2
Belgium and Luxembourg	1.4	–	1.0	0.02	1.9	–	–
Canada	2.5	0.4	1.2	0.1	0.8	0.7	0.4
United Kingdom	2.0	–	0.7	–	0.9	–	1.1
France	10.5	10.0	9.7	15.9	8.4	8.1	6.4
Federal Republic of Germany	15.3	0.4	25.4	2.7	11.6	0.7	22.6

crop produced in the world (70×10^6 t), the majority are consumed fresh or go into wine production (→ Wine). Only those aspects of grape production and products related to nonalcoholic beverages, such as grape juice, are covered here.

Before discussing the quality of the fresh fruit going into processed products, it is important to know some of the major factors influencing the production of temperate fruits. This is necessary because processing can only preserve, not create, good quality. Quality begins with production.

3.1.1. Production

From earliest times, humans have selected and husbanded the plants in their surroundings. They took plants to and from the places they visited and constantly sought ways of increasing their variety and yield. For example, apples, taken from their origin in China, are grown around the world. Through selection, grafting, and hybridization, today's apple is of much better quality than its ancestors.

Some of the major factors to consider in producing high-quality fruit which leads to high-quality beverages are: *Temperature.* Extremely high temperature during growing, or freezes before harvest will decrease quality. *Rainfall.* Heavy torrential rains or long dry summers make it difficult to produce high-quality fruit. *Cultivar.* Selection of scion and rootstock are responsible for genetic control of quality. Cultural practices include every step from selection of resistant cultivars and site selection to the timing of spraying. Growers are responsible for controlling pesticide applications to be sure the fruit contains less than the maximum pesticide tolerance at harvest. Additional information can be found in [28–30]. Further details on apple harvesting can be found in [31], and on grape harvesting in [31], [32].

3.1.2. Harvesting and Transportation

Careful harvesting and rapid transportation to processing facilities ensure that a high-quality starting material will be available for beverage manufacture. Depending on the type of fruit and location in the world, between 30 and 60 % of the fruit's selling price is due to harvesting and transportation costs.

3.1.3. General Fruit Quality

Fruit quality is a multifaceted property which depends partly on the person judging the quality and on the intended use of the fruit. There are cultural aspects of fruit quality like annual bearing, pest and disease resistance, hardiness, and good yield of the trees and a high return per hectare [29]. To be of the highest quality, fruit must be harvested at the correct stage of maturity which may last from as short as 1 or 2 days, but rarely longer than 1 to 2 weeks. There are fresh fruit aspects of quality, such as good handling and storage characteristics, freedom from internal (physiological) defects, and minimal external defects like mechanical injury and dis-

eases. High-quality fruit must have all pesticide residues below prescribed limits.

Postharvest quality deterioration includes: *Aging.* Most fruits are highly perishable, living commodities which respire, oxidizing their internal energy reserves. *Desiccation.* A 5 % loss of water will not only detract from a fruit's appearance but will result in a monetary loss when fruit is sold on a mass basis. A loss of water and turgidity can be caused by bruising during handling. *Decay.* The attack of microorganisms can affect a single fruit or the entire lot.

There are economic aspects to fruit quality. How much a buyer is willing to pay for fruit at a given time depends on the availability of supply, current and projected demand, and any premiums paid for deep rich color, desirable size, high sugar or vitamin content, small seed cavity, etc.

Fruits also have processing quality aspects. Processors need to remember the grower is ultimately responsible for fruit quality. While the processor can preserve the good quality of fruit he receives, he can do little with poor quality raw material. Processing quality includes those subjective attributes already discussed as well as objective measurements like percentage of juice, yield, ^{0}Brix (measurement of percent dissolved sugar or percent soluble solids), percent of acid, pH, color, flavor, and more. Before discussing the quality characteristics of individual fruit, it is important to have up-to-date, accurate, and specific information on government policies, grade, and product standards. Current information on quality standards can be obtained from governmental agricultural officials. Standards among countries in Europe and within the United States can be obtained from addresses given in Section 3.1.7.

Apple Quality. The desirable quality of apples to be processed depends to a certain extent on what product is being made and the properties of the individual apple cultivar. In many countries, the highest quality apples go to the fresh market because growers usually receive the most money there. Highest quality culls go into whole or sliced apples, with the remaining culls going into juice or apple sauce. The apples rejected from these operations are used to make vinegar.

Apples should be left to mature on the trees for optimum quality. Undermature apples are poor in flavor, are hard, and have higher starch and acid content. Overmature apples have a bland flavor, are soft, give low yields of juice, and are difficult to press and clarify [33]. Mature, firm apples should be harvested and handled carefully to minimize bruises and cuts. Bruises usually do not worsen during storage and do not permit increased decay but may require trimming. Cuts in the skin can permit entry of microorganisms that cause spoilage and decay. This in turn can affect loss during storage, product yield, and quality of the finished product [34]. Losses due to improper handling and storage can run as high as 20 %.

Only a few of the differences among apple cultivars are meaningful in utilizing a specific cultivar for a specific processed product. Soluble solids, mostly sugars, are measured by a refractometer and range from 10 to 15 ^{0}Brix. Organic acids, measured by titration, range from 0.25 to 1 %. The sugar-acid ratio (Brix-acid) has been found to be a good indicator of maturity, harvest timing, and product quality [35]. For European cider apples, an average sugar-acid ratio of 12 and total acid of 8 g/L (expressed as tartaric acid) is recommended [27].

Typical apple flavor is important in some products and is formed by a combination of acids, sugars, tannins, and aromatic substances. The quality factors of aroma and taste are affected by differences in cultivars, maturity, starting fruit quality, processing parameters, and storage conditions [36]. In other products like juice concentrate most of the volatile contributions to flavor are lost during evaporation, but can be replaced using commercially available flavors and essences. Maximum juice yield and pressability are important quality factors for apple juice. For additional information on processed apple products see [37], [38]. A list of recommended apple juice varieties for Germany can be found in [27]. The mean and standard deviation for ten parameters of quality have been measured for 15 commercial apple cultivars, grown in 8 seasons over a 3-year period [39].

Apricot Quality. Apricots harvested at optimum ripeness for processing are firm, deep yellow in color, and have good flavor. The firmness measured by a pressure tester ranged from 0.19 to 2.3 kg for apricots ready to process [40]. Fruit

left to mature after the optimum for processing reached maximum flavor and soluble solids but decreased in firmness and acidity [41]. Apricots for puree or nectar should be so ripe they are soft [42]. One of the major quality constraints of apricots is their variable maturity both within an individual tree and across the orchard. Three to four harvests may be necessary to get the best flavored, tree-ripened fruit. Minor to moderate bruising is not a large problem for processed apricot products so mechanical harvesting is satisfactory [43]. Small sized fresh fruit, with a count of more than 30/kg, are often graded out for canning as whole packed apricots or for production of nectar. Details on processing of apricot puree, nectar, and concentrate are found in [42].

Cherry Quality. There are two principal types of cherries: the first has several names, tart or red tart is a preferred name to sour or pie cherries; the second type is the sweet cherry. In the United States, 85 % of the tart and 15 % of the sweet cherries are mechanically harvested [44]. Growers strive for removal of more than 90 % of the cherries in a marketable condition, but late in the season, harvesting machines may greatly reduce the quality.

Tart cherries used for making juice or nectar need to be fully mature and dark in color to give a strongly colored juice. They also need to have a high acid content, good juice yield, and a typical cherry flavor [27].

Sweet cherries for brining and canning also need to be fully mature and dark in color. There is a pronounced increase in the sugars and soluble solids during maturation. In Oregon (USA) Napoleon cherries increase from 12 to 22 % soluble solids from first to last picking. There is a gradual decline in acid content with time. Napoleon cherries go from 0.64 to 0.35 % acid. Some juice processors feel sweet cherries are too low in acid and flavor to make good juice. There is a gradual increase in mass of 0.5 to 2 %/d. Napoleon cherries increase in size 36 % from beginning to full maturity. Size, however, is not one of the main guides to maturity. Firmness is an important quality consideration, but the pressure test is not a good indicator of maturity. Napoleon cherries decrease in resistance 17 % from immature to overripe. During the harvestable period, the decrease is only 6 %. Mature fruit is larger, firmer, more aromatic, and has a more distinctive cherry flavor. Overmature or cull fruit can give cherry juice an off-flavor, while underripe fruit produces a sour, poorly colored juice. Details on manufacture and composition of cherry juice, carbonated cherry juice, and cherry syrup are in [45]. An extensive review on cherry production with less emphasis on processing is available [46].

Grape Quality. There are three grape cultivars of commercial importance, each with its own quality characteristics and products. *Vitis vinifera* cultivars make up about 75 % of the grapes grown in Europe and more than 90 % of those in the United States. They are thick skinned, the skin adheres firmly to the pulp, and the pulp is firm and thoroughly sweet. This cultivar is grown in a relatively mild climate and an example is the Tokay. The *Vitis labrusca* has a relatively thin skin, with the skin slipping easily from the pulp (slip-skin). The pulp is soft and more acidic near the seeds. An example of this cultivar is the Concord, which requires a temperate climate. The third cultivar is *Vitis rotundifolia.* They grow singly or in small bunches, have large seeds, and ripen unevenly. They are Muscadines and have a 'musky' odor. This cultivar grows under a hot, humid climate. The vine is long lived and disease resistant. An example would be the Scuppernong cultivar [29].

Preferred grape maturity depends somewhat on the intended product and cultivar. Grapes should not be picked too early because there is no increase in sugar or color after separation from the vine. Grapes for fresh market are picked somewhat earlier than for juice, before berries begin to shatter from the bunch. Grapes intended for juice production are almost all of the *V. labrusca* type and are picked fully mature. Ripe Concord grapes can have total soluble solids ranging from 15 to 20 % measured by refractometer; for acid, measured by titration, less than 0.85 % tartaric acid is desirable. The minimum acceptable sugar-acid ratio is different for each cultivar [47]. Grapes for juice must possess a good fresh grape flavor. Although the Concord is widely used for juice, it has a strong astringent flavor sometimes described as "foxy." Additional information on grape quality is available [47], [48].

Peach Quality. There are two principal types of peaches, the cling and freestone. Clingstone, where the pit is firmly attached to the flesh, is preferred for canned half peaches and slices. Freestone can be used for nectars. Peaches for processing should have these qualities: large size, symmetrical shape, and a small pit. Yellow-fleshed cultivars with a firm texture to withstand harvesting and hauling are preferred. They should have a characteristic peach flavor and aroma. Peaches are harvested when they are firm and ripe. A significant amount of mechanical harvesting is used. Peaches in Europe are processed into pulpy nectars, which preserve their carotene content. Several peach beverages, freestone peach nectar, pressed peach juice, peach puree, and mixed fruit drinks are made in the United States. Details on these processes are found in [42], [49].

Pear Quality. Pears are grown principally for fresh market with a small amount being processed. Formerly, high-acid cultivars were made into an alcoholic pear cider [27]. Harvesting of pears for use in canning begins when they have reached their maximum size but are still hard and green. Harvesting of pears according to a plunger pressure tester, 8.2 – 9.7 kg, storage at 1 °C for a week or more, ripening at 21 °C at 85 % natural humidity to a 0.9 – 1.4 kg pressure reading gives the best canned pear products [42], [49]. Pears handled in this manner give better quality product than those without 1 °C storage. Preparation of pulpy pear juice, nectar, clear juice, and aseptic canned puree are given in [42], [50].

Plum and Prune Quality. Plums and prunes are terms often used interchangeably for different cultivars. Most plums are canned whole. Most prune cultivars cannot be juiced by pressing and are mostly dried. Selected cultivars of fresh prunes with high acid, and distinctive flavor and aroma can be processed into a pulpy nectar [27], [42]. Dried prunes can be water extracted to produce a prune juice which is rich in minerals and has a mild laxative effect. Details on processing these fruit are found in [42], [49].

3.1.4. Apple Processing

For more than 100 years, apples have been processed by drying and by conversion to cider. This was done to utilize windfall or drops which were low in quality and may have been decayed. Today, high-quality apples are processed into juice, concentrate, fermented cider, wine, apple sauce, and vinegar. Apples are also dried or dehydrofrozen, canned, and baked.

Apple Juice. There are several traditional methods of producing apple juice or unclarified apple cider. These have evolved into modern processing techniques in Europe and have been adapted to the situation in the United States. A generalized flow diagram for apple juice processing is shown in Figure 1 (for additional details, see [38], [51], [52]). Apples from storage, fresh fruit eliminations, or apples directly from the orchard go to the processing plant. First, leaves, grass, and rotten fruit are eliminated. The fruit is thoroughly washed, sorted, and may be trimmed if this can be done profitably. Removal of partly or wholly decayed fruit may be the single most important factor in producing a high-quality apple juice. If the decayed fruit is not eliminated, it produces off-flavors, increases the probability of microbial spoilage, and introduces possible microbial toxins into the finished product [50]. Leaves and grass must be separated as they also can cause off-flavors in the juice. As a general rule, at least three cultivars of 'eating ripe' apples are blended prior to grinding. This gives a desirable blend of the sugar-acid ratio and a preferable aroma. Processing a single cultivar and blending the juice after it is concentrated is not economical.

Sound fruit are sent to a grater or hammer mill to reduce the apples to pulp. If the pulp is too coarse, the juice will be low in yield and soluble solids; if the pulp is too fine, it is difficult to press and the juice has an excess of fine particles.

Enzymatic browning of ground apples takes place in a few minutes and needs to be controlled by inhibiting the polyphenolase enzymes with heat, ascorbic acid, or sulfur dioxide. Ascorbic acid at 0.05 % can be added directly into the grinder but the reaction is difficult to control. The tannins may be oxidized, destroying the desirable amber color. Next the juice is ready to be extracted from the pulp.

Figure 1. Production of apple juice [38], [51], [52]

Juice extraction is very labor intensive, so six methods have been developed and used to reduce labor and increase yield from this operation [51], [52]. Apple juice manufacturers select the method that best meets their criteria.

Figure 2. Newly designed belt press. Apple mash blended with a press aid enters upper left. It is lightly pressed to remove the "free run juice." The press cake is then fed into a high-pressure section which removes the remaining juice. ∗ Courtesy Eimco Process Equipment Co.

1) The *hydraulic press* uses a press cloth placed inside a square wooden rack. The cloth is filled with ground apple pulp then the cloth is folded to completely surround the pulp. A series of racks and cloths are stacked together in preparation for pressing. Pressing usually takes place in two stages. The first, at about 4000 kPa, is applied rapidly to remove the "free run" juice. The second pressing, up to 19000 kPa, is applied slowly and maintained to remove the remaining juice.
2) A *pneumatic press* is composed of a large air inflated rubber bladder and a horizontal screen lined with a press cloth. Pulp is pumped into the space between the bladder and press cloth. Air inflates the bladder and the juice is pressed through the cloth and screen.
3) In the *continuous screw press,* wood pulp as a "press aid" is mixed with apple pulp. This mixture is pressed by the screw past a cone, which partially blocks the exit from the press. The restriction of the cone creates backpressure in the press, forcing the juice from the pulp through the surrounding screen.
4) The *continuous belt press* has apple pulp together with a press aid placed between two continuous belts, then pressed between rollers with increasing pressure. The juice flows out, the pomace is discharged, and the belts are fed back for more pulp (Fig. 2).
5) The *horizontal basket press* is composed of a horizontal cylinder with screen. At one end is a pressing plate and at the other end a stationary press plate. Nylon hoses connect between the two plates. The cylinder is filled with pulp and the pressing plate alternately compresses

so the juice can flow through the cylinder and retracts, allowing the nylon hoses to break up the pomace.

6) The *screen type centrifuge* is a cone-shaped, self-cleaning centrifuge. The pulp is fed in the top and the juice pressed through the screen by centrifugal force.

The pulp exiting the bottom is normally given a second pressing to increase yield.

Pomace from the presses is dried and used to make pectin or cattle feed. Apple juice yield from the presses ranges from 58 to 70 % of the mass of the fruit. The juice is passed over fine screens to remove coarse particles. Pectic enzymes are added to hydrolyze the water soluble pectin, which in turn reduces the viscosity making the juice easier to filter and concentrate [53], [54]. Ultrafiltration can be used to clarify the juice (Fig. 3), or filter aid, usually diatomaceous earth, is added and the juice filtered to give a clear liquid. Screened juice can also be centrifuged to remove most of the small particles, leaving an opaque juice. The juice can be evaporated to give juice concentrate, about 72 °Brix, or pasteurized at 88 – 90 °C for 25 – 30 s to make single-strength juice. Apple essence and flavor compounds are used to add bouquet and increase consumer acceptance. Apple juice is stored cold (4 – 6 °C) to reduce development of browning and off flavors [37]. One report found no difference in the sensory and chemical evaluations after 12 months storage at 3 °C. There were significant aroma changes after 12 months storage at 20 °C [36].

Figure 3. Four-stage, 80 cartridge, sanitary, ultrafiltration system (197 m^2) – used to treat depectinized apple juice (2 – 5 % solids) to produce a "sparkling" clear juice with reduced microorganism counts
∗ Courtesy Romicon, Inc.

Hard Cider and Wine. Alcoholic hard cider, sometimes referred to as cider, and apple wine are covered in more detail under → Wine. European hard cider apples are usually small in size, astringent in taste, and distinctive in flavor. Higher soluble solids means less sugar has to be added before fermentation. American preference for less strongly flavored cider means fresh market apple cultivars may be used. The process is similar to that just described with an additional alcohol fermentation production step.

3.1.5. Grape Processing

World grape production is about 70×10^6 t/a, about 60 % of which is sold fresh, about 40 % goes into wine and 1 – 2 % into raisins and other grape products. Within the EEC, grape hybrids for juice are just being developed. For the United States in 1982, the amount of grapes utilized for raisins was only about half that going into wine; but there were four to five times as many raisins as all other processed grape products combined. Processed grape products besides juice and raisins are juice concentrates, drinks and blended fruit drinks, fruit cocktail, and jelly [24].

Grape Juice. The principal grape cultivar for juice is the Concord. It gives the dark purple anthocyanin color, the astringent-sweet flavor, odor, and other characteristics necessary for quality juice [55].

Processing

is similar to apple juice extraction except that a hot extraction is necessary to obtain the rich purple color, derived from a complex mixture of anthocyanins. Grapes are gently washed with water sprays. Crushing takes place inside a perforated drum where rotating blades and beating bars break the grape's skin but not the seeds and stems. The rotating blades produce a centrifugal action which forces juice and pulp through the slotted drum while the stems and some seeds are discharged out the opening. The juice and pulp are extracted by heating at 60 – 63 °C while being stirred with pectic enzymes in a steam-jacketed kettle. Heating time and enzyme concentration is adjusted to extract the desired color and solubles. Traditionally juice has been

pressed from the pulp by a plate and frame press. Hot pulp and juice are piled on a press cloth which is folded to surround them. A second press cloth is placed on the first and the process repeated. About 50 % of the juice freely flows from the pulp before pressing. Hydraulic pressures of 1380 – 2050 kPa are used to complete the separation of juice, which may yield up to 90 %. Plate and frame presses require considerable time and labor to load and unload plus the juice can pick up considerable microbial contamination from the press cloths. Several other types of presses (discussed in the apple juice section) have been developed to try and overcome these problems. The juice is then pasteurized at about 82 °C, cooled to about 0 °C, and held in a tank for a month to allow the tartrate salts (argols) to crystallize before final clarification and bottling. More information can be found in [49], [56].

3.1.6. Nutritive and Chemical Composition

Temperate fruits are composed of 75 – 85 % water unless they have been dried; then they are only about 5 – 30 %. Water provides the turgidity and crispness when these fruit are eaten fresh. It is the major component of fruit juice and gives shape and mass to other processed products.

The two main dietary contributions of temperate fruits are carbohydrates and vitamins. *Carbohydrates* supply the body's need for food energy. Fruit carbohydrates are mainly in the form of sugars like fructose, glucose, sucrose, and to a lesser extent starch. The mature, 150 g apple shown in Table 2 contained 126.6 g of water; 20 g of the remaining 23.4 g, or more than 85 % of the dry mass, was carbohydrates. Apple juice contains about three times more fructose (4.4 – 8.2 %) than glucose (1.3 – 2.0 %) or sucrose (1.7 – 4.2 %) [52]. The ratio of these sugars is one of the important parameters in determining the authenticity of fruit juice [58].

Vitamin C (ascorbic acid) and vitamin A are present in temperate fruit (Table 2). Some of the richer sources of *vitamin C* are apricots, peaches, and cherries. Vitamin C is essential for healthy teeth, bones, and gums, and it aids in wound healing. Those factors affecting vitamin C content of the fresh fruit have been reviewed [59]. Apple juice may be fortified with vitamin C because apple juice contains so little compared to citrus juices, and also it helps reduce settling in cloudy juice.

Vitamin A occurs as carotene in apricots and peaches. It is important for vision and maintaining healthy linings of the mouth, nose, throat, and digestive tract.

Temperate fruits contain small amounts of several *minerals.* Dried fruits contain iron. From 150 g of raisins, 9.5 mg of iron are supplied, 150 g of dried apricots provide 8 mg, and 150 g dried peaches 5.3 mg. Reviews of the nutrition and composition of raw and processed products from temperate fruits have been published [60], [61]. Processing involving heat and storage has a complex effect on nutrient retention [62].

3.1.7. Regulations

Regulations from an international to a local level are critical to temperate fruit processing and marketing. In order to get the most relevant and up-to-date information, the following organizations should be contacted. Background information for regulations within the United States can be found in [63].

Regulatory agency addresses:

– For standards within the United States:

1) *USDA,* Chief, Processed Products Branch, Fruit and Vegetable Division, Agricultural Marketing Service, U.S. Dept. of Agriculture, Room 0709, South Building, Washington, DC 20250, USA
2) *FDA,* Director, Division of Food Technology, Food and Drug Administration, 200 C Street S.W., Washington, DC 20204, USA

– For standards within the European Economic Community:

1) *CODEX Regulations,* Executive Director, International Organization Affairs, Room 6552, Office of Int. Cooperation and Development, U.S. Dept. of Agriculture, Washington, DC 20230 USA
2) *EEC Regulatory Address,* Mr. A. Korth, Verband der deutschen Fruchtsaftindustrie, Konstantinstr. 3, D-5300 Bonn 2, Federal Republic of Germany

3.2. Subtropical Fruits

Citrus fruits are one of the largest and most important groups of fruits for juice processing. The place of origin of nearly all species of citrus fruits was probably in warmer Asian regions: Southeastern China, India, and Malaysia. Nowadays citrus fruits are grown in all tropical and subtropical regions (i.e., between the latitudes 40 °N and 40 °S); the warmer areas of North America, South and Central America, the Mediterranean, the Far East, and a few other Southern Hemisphere countries, such as South Africa and Australia.

Important commercial citrus fruits can be classified into four main groups: (1) oranges, (2) tangerines, (3) grapefruits, (4) lemons and limes. World citrus production in 1983 was estimated at 55×10^6 t; oranges (69 %), tangerines (14 %), grapefruit (8 %), lemons and limes (9 %). More than 125 countries and territories in the world produce some type of citrus fruit. The following top ten producing countries account for nearly two-thirds of the total: United States (22.2 %), Brazil (18.6 %), Japan (6.6 %), Spain (5.5 %), Italy (4.8 %), Mexico (4.0 %), Argentina (2.8 %), Israel (2.6 %), Egypt (2.6 %), Morocco (1.8 %) [64], [65].

In 1946, a method for producing a high-quality frozen concentrated orange juice (FCOJ) was developed [66]. Juice was concentrated under vacuum at a low temperature, fresh cut-back juice freshly squeezed (nonpasteurized) was added to the over-concentrated product to bring it back to the desired concentration and to restore fresh flavor and aroma, and the final material was packed as a frozen product. This momentous discovery was the major stimulus for the development of more efficient juice extractors, finishers, evaporators, and other important juice processing equipment, and for the dramatic increase in worldwide orange production especially in the United States and Brazil.

Approximately 40 % of world citrus production is processed into juices and concentrates. Processed oranges and tangerines represented over 84 % of total processed citrus fruit in 1982. United States and Brazil account for nearly 80 % of the total juice production [64].

3.2.1. Quality of Fruit for Processing

From exterior to interior, the major parts of the citrus fruit are:

1) peel or rind (epidermis, flavedo, oil glands, albedo, and vascular bundles)
2) segments or sections (segment wall, juice vesicles, and seeds)
3) core (vascular bundles and parenchymous tissue).

*Flavedo*is the outer, colored skin which is covered with a thin, wax layer and contains essential oils as well as carotenoids (coloring matter). *Albedo* is the thick, white porous inner skin which is closely attached to the flavedo. The thickness of this albedo layer in orange and grapefruit is a predominant factor in determining the proper adjustment of extractor parameters for optimum quality and juice yield. *Segments* are composed of juice vesicles which are enclosed by the segment wall. *Seeds* are contained in most fruit segments but some hybrids are wholly or partially seedless. The *core* is the fruit axis. Bitter substances (polyphenols) are contained in skins, vesicle membranes, albedo, and core; consequently, extraction treatments minimize introduction of undesirable substances from these tissues into juice for processing [67].

In commercial operations, average juice yield from oranges varies from 43 to 60 %, with residues, i.e., peel, pulp, and seeds, left after juice extraction, 40 – 57 wt % [68]. The proximate compositions of various citrus juices are shown in Table 3 [69], [70].

The quality of citrus juice is judged by its color, flavor, °Brix/acid ratio, and defects. A good quality juice should possess good color (the appearance of fresh juice), should be free from defects (e.g., seed fragments, insect fragments), and should have good flavor, proper °Brix value and °Brix/acid ratio, and proper pulp and oil contents. Therefore, every step of processing must preserve good quality and minimize introduction of detrimental components.

The fruit used should be whole, mature, sound, and recently harvested. Before harvest, fruit for processing must meet certain minimum maturity requirements established by regulatory agencies. Those requirements may vary from one citrus-producing area to another, but standards are designated for nearly all the citrus

Table 3. Proximate composition of citrus juices, g/100 g [69], [70]

Juice	Water	Protein	Fat	Sugar	Acid	Vitamin C
Orange	88.3	0.6	0.2	9.3	0.6 – 1.6	0.05
Tangerine	88.9	0.5	0.2	9.2	0.6 – 1.6	0.04
Grapefruit	90.2	0.5	0.1	6.0	1.2 – 2.2	0.04
Lemon	87.6	0.4	0.2	3.2	4.0 – 6.0	0.05

processing areas throughout the world. Such requirements are usually based on: color break, minimum juice content, minimum acid content, minimum percentage of total soluble solids, and °Brix/acid ratio.

Figure 4. Basic elements of the citrus processing industry
▭ Intermediary product; ▭ End product; —- Juice line; - - - - - Byproduct line

3.2.2. Processing

Processing of citrus fruit can yield many different products (see Fig. 4). In the 1950s the citrus industry considered nonjuice components of fruit as having little or no commercial value. Juice remains the main product of citrus fruit, but now commercial processing of other components also is important economically. Processed citrus *juice products* include: single strength, concentrate, comminuted, orange pulpwash, bases, crystals, and segments. Production of pure juice, either single strength (S/S) or concentrate, probably accounts for over 90 vol%. Byproducts and other *nonjuice containing products* of citrus fruit include: oils, essences, D-limonene, peel and pulp for cattle feeds, molasses, alcohols, pectin, and flavonoids [71].

A basic citrus processing plant generally includes the following operations:

- bulk concentrate juice processing
- pulpwash recovery and addback
- cold pressed oil recovery combined with D-limonene recovery
- essence recovery
- animal feed processing from peel and rag wastes.

The variations to those basic operations include:

- concentrate packed in consumer sized containers
- single strength packed in consumer sized containers for the local market only both directly from fruit and reconstituted from concentrate
- bulk concentrate packed for remanufacture.

Major unit operations involved for citrus juice processing are: extraction, finishing and centrifuging, pasteurization, evaporation, freezing, packing, and storage.

Extraction. Three major types of juice extractors are commonly used in the citrus juice industry. They are fast, rugged, and easy to clean and to adjust to fruit of different sizes and characteristics.

Rotary Juice Press (Fig. 5). This was the first machine developed for commercial juice extraction. The process involves cutting the fruit in half, then passing the fruit halves between rotating cones and the cups which press out the juice. In another version the cut fruit is pressed between two rotating cylinders. In the latter case, oil has to be extracted prior to juice extraction. The major disadvantage of the method is the relatively low juice yield. The rotary press has been generally superseded by more modern and sophisticated equipment in most processing plants in the United States, but it is still used commercially in Italy, Spain, and Central and South America.

Figure 5. Rotary juice press
∗ Courtesy S. A. Bertuzzi

In-line Extractor, FMC (Fig. 6). This machine is used worldwide. The unique aspect of the FMC machine is that juices are extracted without first halving the fruit. The main steps involved are:

1) Fruit is placed in lower of two cups formed by a series of metal fingers.
2) Similar designed upper cup descends on fruit and as it closes the steel tube opens a hole in bottom of the fruit.
3) Fingers of two cups interlock crushing fruit and expelling juice, pulp, and some rag into a perforated steel tube.
4) Piston in tube compresses fruit flesh forcing juice and some juice sacs through perforated inner cylinder walls into juice collector tube. Remaining pulp and peel plug then eject from bottom of steel tube.
5) Peel and rag forced through cup fingers release oil, which is washed away and collected separately as a water emulsion. Peel is ejected from top of cups.

The major advantages of the FMC machine are its elimination of the halving step, its minimization of contact between juice and other fruit components, especially flavedo and albedo, its simultaneous oil separation, and its prefinishing ability. Both quality and juice yields are excellent depending on proper adjustment of the clearance of the inner pistons. Disadvantages are its cost and complexity. The fact it lacerates the peel can be either an advantage or a disadvantage depending on subsequent peel processing.

Extractors, Brown (Automatic Machinery Corp.). These machines are also used worldwide. There are several models of different sizes and capacities. However, the basic principles are similar. As in the case of the rotary press, fruit are initially cut in half. The halves are then held by rubber cups, while plastic reamers enter and express the juice from the fruit. This all occurs as the cups and reamers are rotating on a large turntable, or in a vertical plane. Juice and pulp collects in a pan, while rag and peel halves are ejected.

Both quality and juice yields from this process are excellent. Oil content is low because few oil cells (flavedo oil glands) rupture. Oil must be extracted separately. However, the company has developed an excellent machine for this purpose.

The disadvantages, like the FMC in-line extractors, are relatively high cost and complexity.

Finishing and Centrifuging. These two operations complete the basic separation process initiated and are largely accomplished by extraction. Both operations separate pulp from raw juice.

Primarily two machines are available for *finishing* raw juice. These are manufactured by the two major extractor manufacturers, i.e., Brown and FMC. Both machines operate on a rotating screw principle (Fig. 7). Raw juice enters at one end. Pulp is squeezed out at the other end, while finished juice passes radially through sieving cylindrical shaped screens. Finishers can also be adjusted to influence the amount of juice recovered. A paddle finisher (Fig. 8) provides more gentle finishing.

Figure 6. Principles of FMC in-line extractor
∗ Courtesy FMC Corp.

Figure 7. Brown model 2503 screw finisher
∗ Courtesy Automatic Machinery Corp.

Figure 8. Brown model 200 paddle finisher
∗ Courtesy Automatic Machinery Corp.

The *centrifuge* completes the separation of pulp particles from juice prior to evaporation. Standard finishing is generally capable of reducing pulp content of juice to about 12 %. Florida juice specifications state this level is acceptable. As a result some Florida plants do not centrifuge their juice. However, European standards generally require lower pulp content (as low as 3 – 5 %). Only centrifuging can ensure these low levels.

Centrifuging offers other advantages. It eliminates undesirable particles, broken seeds, etc., which finishing will not remove. Thus, the resulting juice is of a higher quality. It also permits the juice to be concentrated to a higher °Brix with lower viscosity. However, centrifuging does reduce overall yield.

Evaporation. Vacuum evaporation of water is the key concentration activity. In theory, water can be removed by freezing as well as by evaporation. In practice, evaporation is the only economically feasible method in present commercial use for citrus.

Freeze concentration has several advantages over evaporation:

– Low process temperatures, normally between 0 °C and – 15 °C depending on the type of product, result in better product quality.
– The absence of liquid-vapor interfaces, combined with a totally closed system, results in no losses of volatile aroma components.

The disadvantages are higher solids loss and higher energy costs than by evaporation. An

improved freeze concentration process, developed by Grenco Special Applications B.V. in the Netherlands, may overcome the drawbacks of freeze concentration. Freeze concentration was tested in the citrus processing industry [72].

The purpose of concentration operations is to convert single-strength juice into a product form that will be more economical to store, distribute, and sell. Concentration by *evaporation* involves enzyme stabilization, pasteurization, and deaeration in addition to concentration. Traditionally the former operations were performed separately from evaporation. Now all three occur simultaneously during evaporation.

The evaporation process is critical for two reasons:

1) *Economics* – the fuel costs necessary for evaporation represent by far the largest operating cost of all the juice processing within the concentrate plant, excluding the extractor rental fee.
2) *Technology* – evaporation is a fairly complex process calling for considerable technical skill and experience. It subjects the juice to high temperatures. As a result evaporation greatly influences the quality of concentrate it produces.

There are three major types of evaporators each associated with a specific, largely specialized manufacturer.

TASTE Evaporator. The TASTE (thermally accelerated short time evaporator) is produced by Gulf Machinery of Clearwater, Florida (USA), and is the most common evaporator used worldwide. It accounts for around 80 % of the world market for citrus evaporators. The TASTE evaporator was developed in the late 1950s and early 1960s.

A typical TASTE evaporator, 5-effect, 8-stage, is shown in Figure 9. The word "stage" indicates the sequence of product flow as it travels through the evaporator. The term "effect" indicates the sequence of vapor (or steam) flow through the evaporator. The roman numerals as in Figure 9 indicate the effect while the arabic numerals indicate the stage. Thus, the number of stages is merely the number of bodies in series in terms of juice flow. The number of effects represents the number of different pressure drops being used for concentration.

TASTE evaporators use long vertical tubes, with inside diameters of 22 – 46 mm and lengths of 3 – 18 m. Total system heights are 18 – 35 m. Juice enters the evaporator by a countercurrent flow through interstage heaters which preheat the juice using vapor from the previous effect. The juice then enters the top of the first effect tube bundle through a nozzle type distributor, and travels downward through the tubes, where it absorbs heat from the steam on the outside of the tubes. At some stages, the juice is reheated in the reheater to provide sufficient superheat so that the liquid will flash and distribute itself uniformly upon entering the subsequent stage. Evaporation takes place on passage down the tubes, not as a liquid on the tube wall, but as a mixture of juice and vapor; heat is transferred to the turbulent mixture. The exit velocity from the tubes is ca. 20 – 100 m/s [73].

On leaving the tubes, the liquid and vapor mixture travels into the centrifugal-type vapor separator connected to the bottom of each effect. There is no juice level in the separator. The juice from the first effect separator is pumped to the top of the second effect where it enters through another nozzle, flashes, and evaporates in a similar manner. The vapor from the first effect supplies the heat for the second effect and so on for subsequent effects [74], [75].

Most TASTE evaporators are forward flow and single pass (no recirculation). There are normally 4 – 7 effects with the last composed of 1 – 4 stages. They are capable of concentrating the juice from 12 to 72 °Brix. For orange juice, the concentrate from the last stage is ca. 60 – 65 °Brix, and is at a temperature of 35 – 38 °C. The residence time from the first stage to the last stage is ca. 6 – 8 min. From the last stage, the concentrate is pumped into a flash chamber maintained at a high vacuum to chill the juice to 4 – 10 °C before exit. Another 1 – 3 °Brix increase in concentration results from this method of cooling. Practically instant cooling is achieved in the flash chamber. No heat transfer surfaces are required. This method of cooling minimizes heat damage which might result from high-temperature evaporation and can be used with viscous materials. The concentrate is further cooled to – 5 to – 10 °C prior to pumping into bulk storage tanks.

The evaporation to steam ratio is roughly $0.8\,N : 1$ where N is the number of effects, i.e.,

Figure 9. Schematic of typical TASTE evaporator (5 effect – 8 stage)
∗ Courtesy Gulf Machinery Co.

for a 4-effect evaporator the evaporation to steam ratio is 3.2 kg evaporation to 1 kg steam.

Plate Evaporator, APV. This type of evaporator is produced by APV with headquarters in the United Kingdom and manufacturing operations around the world.

The APV company developed their first plate evaporator in 1957. These evaporators are widely used in many countries in the dairy, food, fruit juice, pharmaceutical, and chemical industries.

The origins and basic concepts of the plate evaporator are very similar to those of the tubular, i.e., TASTE type evaporator just described. The major difference is that banks of gasketed plates held together in a frame replace the tube bundles and tubular bodies. Steam and juice pass between alternate plates.

The evaporation to steam ratio is about the same as the TASTE evaporator or slightly better. Higher efficiency vapor recompression is also available.

Centrifugal Evaporator, Alfa-Laval. This type of evaporator, produced by Alfa-Laval with headquarters in Sweden and worldwide manufacturing operations, differs significantly from the previous two. The main variations of the Alfa-Laval evaporator are: evaporation and centrifugal separation occur simultaneously (and continuously); residence times are short (1 – 2 s compared to several min) and temperatures low (45 °C compared to 80 °C); technology and economics are comparable to single-effect evaporation only.

Centritherm type evaporators were specially developed as single-effect, short time, low-temperature units to be used where conven-

tional evaporation methods did not give good results. The evaporation to steam ratio is no better than for a single-effect evaporator, i.e., about 0.9 : 1. Because of low steam economy, these evaporators have limited application in the citrus industry.

For further information on concentration and citrus evaporator technology see [73], [76].

The final operations after evaporation involve blending, packaging, storing, and shipping of the concentrated juice product. Concentrate to be used for reprocessing can be stored in drums at about − 20 °C. Tank or bulk storage is used for large operations at storage temperatures of − 5 to − 10 °C.

3.2.3. Processed Citrus Products

Citrus juice production can be described by the form in which the extracted juice is initially produced and stored. Market volumes can be measured by the retail form of the juice. Reprocessing activities which link the two could include reconstitution (i.e., dilution from concentrate to single strength) and/or consumer packaging (i.e., repackaging from bulk to consumer sized containers). Processing characteristics for different types of juice have been described [77].

The three major types of juice are:

1) Nonreconstituted single strength, i.e., produced direct from fresh fruit without evaporation;
2) Reconstituted single strength, i.e., produced from concentrate;
3) Concentrate, i.e., juice that has passed through evaporation.

There are three variable aspects of consumer packaging. These are:

1) Process used for filling – hot pack, refrigerated (chilled), or aseptic;
2) Type of container – can, glass, cardboard, or plastic;
3) Size of container – 165 mL through 19 L.

The estimated citrus juice production patterns and market volume are shown in Table 4. Citrus juice production patterns are illustrated in Figure 10.

Table 4. Estimated citrus juice production patterns and market volumes [78–80]

Patterns	Market volume, %∗			
	United States		World	
	Orange	Grapefruit	Orange	Grapefruit
Nonreconstituted S/S ∗∗	19	59	14	55
Reconstituted S/S ∗∗	14.5	20	29	24
Concentrate	66.5	21	57	21

∗ Expressed as % of all juice
∗∗ Single strength

Several factors affect the quality and stability of the final processed products. The two most important factors are dissolved oxygen and heat treatments. Oxygen must be removed because of its adverse effect on color, vitamin C, and citrus oils. Oxygen can be removed by deaeration; proper packaging design prevents it from re-entering the product.

Citrus juices are perishable at room temperature and can deteriorate in quality even in aseptic packages. Their delicate fresh aroma and flavor may be lost or damaged at room temperature. The extracted juices are usually pasteurized and chilled as rapidly as possible to minimize the loss of flavor.

The purpose of pasteurization is to destroy spoilage organisms, inactivate enzymes, or both. Heating to 65 °C will destroy most spoilage organisms, but temperatures as high as 92 °C for about 30 s may be required to inactivate the natural enzyme, pectinesterase, and stabilize the juice. The time required can be lowered by using higher temperatures. The temperature necessary to stabilize the juice is also pH dependent. Juices at higher pH require higher temperatures for stabilization. Pasteurization requirements for different products have been reviewed [81].

Concentrate Blending and Reprocessing. The purpose of concentrate blending is to achieve a uniform, high-quality final product prior to cooling, storage, distribution, and sale.

A process known as *cut-back* involves addition of fresh juice to the concentrate. This process was the traditional method of restoring volatile aromas and essences to the concentrate and is still used by some processors in Florida. However, with the development of essence recovery systems, the use of essence and oil in-

Figure 10. Citrus juice production patterns
∗ Single strength

stead of cut-back allow the concentrate to be maintained at high °Brix, reducing distribution costs. For this reason, virtually no plants use cut-back in Brazil.

Essences are stored as two separate phases: water phase essence and oil phase essence. These are generally added back to concentrate during blending along with cold-pressed oil, obtained from peel rather than juice. However, various combinations of essence and cold-pressed oil can be added back depending on the type of concentrate, time of year, customer requirements, etc. Blending is probably the most important operation for concentrate reprocessing. Technical aspects of reconstitution and blending of concentrate for consumption as a single strength juice have been described [82].

3.2.4. Chemical and Nutritive Data

Citrus juice is a complex mixture of hundreds of chemical constituents. Many of these relate to the quality and nutritive value of these products [83].

Citrus fruits have long been recognized as excellent sources of ascorbic acid (vitamin C), which is the most abundant vitamin in citrus fruits. Citrus fruits are also quite rich in the mineral element, potassium. Other nutrients in orange juice that are of dietary significance, according to standards set by the U.S. Food and Drug Administration [84], i.e., they are present at a level of 10 % or more of the U.S. RDA (Recommended Daily Allowance) per serving, are folic acid and thiamine (vitamin B_1). A serving size for orange juice is generally 177 mL. Average nutrient delivery per serving of reconstituted FCOJ (12.8 °Brix) in relation to U.S. RDA is shown in Table 5 [84], [85]. For more information on nutritive data, see [86], [69], [87].

Table 5. Average nutrient delivery per serving of reconstituted FCOJ (12.8°Brix) in relation to United States RDA

3.3. Tropical Fruits

There is no fine dividing line between a tropical and subtropical fruit, but a tropical fruit is generally defined as one which cannot be grown at temperatures which fall much below 5 °C [88]. The vast majority of tropical fruits thrive best in a region lying between the Tropic of Cancer and the Tropic of Capricorn; examples of tropical fruits would include banana and plantain, pineapple, mango, guava, Annona (soursop, cherimoya, custard apple, sugar apple), sapodilla, and papaya. Although many subtropical fruits, for example citrus, passion fruit, and longan grow also in tropical regions, they are classified as subtropical because they can tolerate temperatures around − 4 °C for the short term.

The entire topic of tropical fruit juices cannot be covered in this article. Therefore, the pineapple has been selected to illustrate the various steps in the processing of tropical fruit into beverages.

3.3.1. Introduction

The pineapple, *Ananas comosus* (L.) Merrill, is a native of tropical America, and appears to have originated in Brazil and/or Paraguay. *Ananas* is derived from the name used by the Guarani Indians of Paraguay [89]. Columbus found it cultivated in the West Indies in 1493, and by 1600, Portuguese sailors had carried it to Java, Malaysia, and India.

The pineapple is a multiple fruit composed of a large numer of fruitlets growing from a central stem called the core. Each fruitlet is a portion of a small flower which forms off the stem before the fruit matures. All pineapple cultivars examined produced functional pollen and egg cells but all are self-incompatible; therefore, they cannot set seed from self-pollination. The five groups of cultivated pineapples are Spanish, Queen, Abacaxi, Cayenne, and Maipure. The pineapple is best suited to a mild tropical climate with temperatures between 16 and 32 °C.

World production of pineapples in 1982 exceeded 5×10^6 t. The major producers with production in 10^3 t were [90]: Thailand (1824), Philippines (890), United States (560), Mexico (550), Ivory Coast (320), South Africa (232), Malaysia (170), Australia (125), and Taiwan (99). Total production of pineapple products ($\times10^3$ t) were: canned pineapple (804), pineapple juice concentrate (38), single-strength pineapple juice (195), and fruit salad, frozen pineapple, and other products (6).

Pineapples produced commercially in the United States are grown almost entirely in Hawaii (Smooth Cayenne variety) and Puerto Rico (Red Spanish and Smooth Cayenne varieties). United States pineapple products are destined primarily for the domestic market, but some are exported to Canada, Europe, and the Middle East.

3.3.2. Quality of Fruit for Processing

Nutrition, climate, variety, geographical growing area, season, and ripeness are important factors affecting pineapple fruit quality. The ultimate quality of pineapple juice is primarily dependent upon the relative ripeness of the fruit. Selection of individual fruit for harvest and processing requires considerable human judgment because fruit in the field does not ripen simultaneously.

Additionally, pineapples do not ripen after harvest; therefore, fruits harvested prior to optimum ripeness remain inferior and those harvested at an over-mature stage exhibit a poor flavor. Fruits destined for the fresh market are generally harvested at a less ripe stage than those going to the cannery.

Flavor and composition of pineapple juice mimic the flavor and composition of the fresh fruit from which it is prepared [91]. Pineapple fruits which have a °Brix/acid ratio of about 20 produce high-quality juice. In Hawaii the pineapple reaches peak fruit quality in June and July; during winter the fruit tends to be pale, lower in °Brix, higher in acid, and lacking in volatile flavor components.

3.3.3. Processing

Pineapple juice may be regarded as a byproduct resulting from the preparation of primary pineapple products such as slices, chunks, and crushed meat. Juice is primarily derived from cores, juice trimmings, eradicator meat, small

fruit, juice drained from crushed pineapple, and juice drained from eradicator meat. The FDA Standard of Identity [92] for pineapple juice is defined as the "juice intended for direct consumption, obtained by mechanical process, which may include centrifuging but not filtering, from the flesh or parts thereof, with or without core material, of sound, ripe pineapple. Canned pineapple juice contains finely divided insoluble solids, but it does not contain pieces of shell, seeds, or other coarse or hard substances." Added sweeteners, vitamin C, and dimethyl polysiloxane (defoaming agent) may be added to canned pineapple juice.

A simplified schematic showing the processing steps in the preparation of commercial pineapple juice is shown in Figure 11. Harvested fruit is unloaded from bulk bins at the cannery, mechanically graded for size, washed, and sent by conveyors to Ginaca machines (FMC, Madera, Calif.) (Fig. 12). These machines are adjusted to accommodate fruit of varying diameter sizes; that is, specific machines will process only fruit within a specified diameter range. The Ginaca machine is fully automatic and removes the inedible component of the fruit from the edible parts; it processes the fruit by cutting off both ends, coring the cylinder, and trimming the cylinder from the shell. One part of the machine, called an "eradicator," shaves the juicy meat portion (eradicator meat) from the shell for use in crushed pineapple or juice. The meat adjacent to the shell contains a large amount of valuable aromatics used in making a quality juice [93]. The core is used for the preparation of crushed pineapple or juice. The major product from the Ginaca is the pineapple cylinder, which is conveyed to trimming tables where each cylinder is hand-trimmed to remove the last traces of shells and blemishes. The cylinders are subsequently washed, sliced, and packed in cans. Slices that are broken, too thick, or too thin are unsuitable for the sliced product, but can be used for crushed pineapple or juice products. The fruit production from a single Ginaca machine is up to 150 t/d; about 75000 L of juice are produced [91].

The next primary stage in the preparation of the pineapple juice beverage is the disintegration of all solid constituents remaining after preparation of the basic pineapple products (slices, chunks, and crushed meat). Prior to disintegration, a first stage screw press may be used to remove part of the extractable juice; the screw press reduces the amount of fine solids that would have to be removed later to produce an acceptable juice. The disintegrating device commonly used is the Reitz disintegrator; this machine is comprised of a rotating shaft with fixed or pivoted disintegrating arms to which the fruit is introduced axially. The arms are surrounded by a screen (0.64 cm opening) through which material passes after having been appropriately reduced in size. The material emerging from the disintegrator is a free-flowing juice containing small sharp free-draining fibers [94]. Although many pine-apple canneries use the Reitz disintegrator, some prefer a Schwarz extractor which produces a liquid that goes directly to a juice tank and a coarse pulp that is then fed to a press.

The slurry material emerging from the disintegrator passes through a heat exchanger (about 60 °C) which increases cell wall breakdown, releases more juice, and inactivates the protein-digesting enzyme, bromelain. The heated juice then goes into a finisher (generally a screw type), which separates the liquid from the comminuted solids. The separated liquid flows into centrifuges (Sharples, Merco, or Westphalia continuous types) to remove excess fiber and other material.

Juice separated from insoluble tissue components by screw extractor and centrifuge machines is fed into a central holding or blending tank. This tank allows for the mixing of constituents of several lots of fruit. Additionally, liquid discharges from various process lines (crushed meat, slices, cores) may be collected separately and characterized for taste, solids content, °Brix/acid ratio, flavor quality, etc. The liquid discharge from each line may then be judiciously blended to create a juice product with characteristics best suited for that product, i.e., having the desired levels of sugar, acid, insoluble solids, flavor, and aroma.

In the preparation of single-strength juice, cans are filled at about 60 °C with the juice from the blending tank and closed. The juice is pasteurized by passing the closed cans through a standard reel cooker and cooler combination; processing time is regulated to bring the temperature of the juice to no less than 87.7 °C [91]. Pineapple concentrate is produced from single-strength juice with equipment similar to

Figure 11. General processing steps in the preparation of pineapple juice

Figure 12. Ginaca machines
∗ Courtesy AVI Publishing Co.

that used in the preparation of citrus concentrate (see Section 3.2.2.).

Types of Products. The major pineapple juice products are canned single-strength, concentrate, and nectar. The standard of quality for canned single-strength pineapple juice [92] is: soluble solids content without added water shall not be less than 10.5 °Brix; the acidity is not more than 1.35 g of anhydrous citric acid per 100 mL juice; °Brix/acid ratio is not less than 12; and finely divided insoluble solids is not less than 5 % nor more than 30 %. Pineapple concentrates are produced at °Brix values of 46 ° (3 to 1 for reconstitute), 61 ° (4.5 to 1), and 72 ° (6 to 1). Mixed nectar products containing pineapple pulp as one of the ingredients are available, but a pure pineapple nectar is not sold [95].

Chemical and Nutritive Data. The composition and nutritive value of pineapple juice is not only related to the fruit from which it is derived, but also is related to processing conditions, storage, and type of container in which the juice is marketed. An approximate composition of frozen pineapple juice is shown in Table 6 [96]. Pineapple juice is well buffered (range of about pH 3.3 – 3.7) and the average free acid content averages about 0.8 %. The major acids in descending order are citric (0.7 – 0.9 %), malic (0.2 %), and ascorbic (0.008 – 0.02 %); small amounts of oxalic, malonic, succinic, galacturonic, tartaric, and glycolic are also present [97]. The soluble solids content of pineapple juice is mainly derived from carbohydrates, in particular, the mono and disaccharides. Representative values of °Brix (10.8 – 17.5), glucose (1.0 – 3.2 %), fructose (0.6 – 2.3 %), and sucrose (5.9 – 12.0 %) have been reported [98]. Pineapple juice is an attractive food because of its good taste and pleasing aroma. Numerous studies on the aroma constituents and other aspects are available [91], [98], [99].

3.4. Vegetable Juices

The processing of vegetables into juice products has many features in common with fruit juice processing. Juice is derived from a fresh vegetable by comminution, followed by separation of the large colloidal particles, or by pressing the comminuted vegetable to obtain a clear juice. Comminuting machines express about 60 –90 % of the vegetable into a product of juice-like consistency. Quite often, the suspended solids are allowed to remain in the juice because much of the flavor, aroma, and mouth-feel is due to these solid constituents.

The maceration of a vegetable liberates enzymes. Unless heat treatment is used to deactivate them, either before or immediately after the cellular disruption process, detrimental juice quality changes will result. The processing of low-acid vegetables (tomato, rhubarb) or the addition of acid (commonly HCl) to a vegetable will allow for lower processing temperatures. However, for most vegetables, high-temperature heat processes are required to inactivate enzymes and to kill spores of spore-forming bacteria that may germinate in neutral or slightly acidic vegetable products [100].

Tomato juices represent the largest and best known segment of the vegetable juice market. Tomatoes are used in making tomato juice, cocktails, and tomato juice blends. Because of the prominence of tomato juice, a brief discussion of the processes involved in its preparation follows. Tomatoes used for preparation of tomato

juice possess high color, rich flavor, and high total acidity. These *quality attributes* are primarily influenced by variety, maturity, climate, geographical growing area, and cultural practice. In the *juicing process,* tomatoes are first chopped into fine pieces or coarsely ground, and then extracted by a pressing action, or they are sieved under great agitation as is normally encountered with a pulper or finisher. The pressing action of a screw-type juice extractor yields an average of about 79 % juice, whereas a paddle pulper and a paddle finisher give an average yield of about 82 % [101]. Either type of extractor can be preset to yield either a high or low percentage of juice.

Consistency is an important quality factor; tomato juice with proper consistency has a smooth mouth-feel and its solids will not separate readily from the serum [102], [103]. Tomato juice consistency can be increased by addition of acid to the tomato tissue immediately prior to or during comminution and heating [104], [105]. The method of manufacture, i.e., by use of the cold break method or the hot break method, also affects consistency of the tomato juice product. In the *cold break method,* tomatoes are macerated at ambient temperature and the resulting pulp is pressed through wire mesh screens to separate juice from seeds, skins, and cores. This process yields a juice of low consistency because of pectin degradation by naturally occurring pectic enzymes. In the *hot break method,* the same mechanical steps are used but heat (71 – 88 °C) is applied during maceration or immediately after to inactivate the pectic enzymes. The juice obtained by the hot break method has a higher consistency and is generally preferred by the industry.

During the maceration, finishing, and filling steps, deaerators are often used to remove dissolved or occluded air. Deaeration minimizes vitamin C loss and off-flavor development. In addition deaeration may be used after pasteurization or high-temperature presterilization to remove air incorporated by pumping, to cool the juice to filling temperatures, and to prevent foaming in the filler bowl.

Tomato juice may also be homogenized to prevent settling of solids and separation of serum. In this process, juice is routinely forced through narrow orifices at pressures between 70 and 98 kg/cm^2 to finely break up the suspended solids. Viscosity of juice is increased and a smoother consistency is attained.

Prior to packaging, juice is sterilized at a recommended temperature of 121 °C for 0.7 min and cooled rapidly to about 93 °C. The juice is conveyed to filler bowls where salt is ordinarily added or the salt may be added to individual cans (0.5 – 1.25 wt %). Finally the juice is packed in plain or enameled tin cans or in glass.

A more extensive coverage of other vegetable juice products, such as fermented vegetable juices, nonacid vegetable juices, and soybean milk, may be found elsewhere [4], [100].

4. Sweet Carbonated and Non-carbonated Beverages [106–108]

The most important requirements for sweet nonalcoholic beverages (soft drinks) are that they must be refreshing as well as pleasing in taste and odor. The taste factors perceived by the tongue are sweet, sour, bitter, and salty. These factors are influenced by beverage ingredients, such as sugar (sweet), phosphoric and citric acids (sour), quinine and caffeine (bitter), and various salts.

The odor perceived by the nose is determined predominantly by the flavoring ingredients, as will be discussed in Section 4.2, and to a lesser extent, also by fruit juices, caramel, etc.

Other food additives play an important role in soft drinks as well, and according to their functional properties include preservatives, antioxidants, emulsifiers, food colors, sequestrants, stabilizers, and buffers.

The soft drink industry is based on two different technologies, namely for carbonated products and for still drinks. This industry is the major user for most of the ingredients mentioned previously.

History. The oldest reference to soft drinks is probably in the *Old Testament* where unfermented "wines" are mentioned. Lemon juice is also one of the oldest bases for soft drinks, such as the "lemonata" from Sicily. Still lemonade was well known in France and Italy at the end of the 16th century, and in Britain by the end of the 17th. One of the first legal regulations on record for such products is from Paris in 1676 regarding the sale of "limonade". The history of sweetened carbonated beverages is not quite clear;

it started around 1800 after the skills involved in making artificial mineral water were developed. LEONHARD THURNEYSSER is usually credited with the first attempts to make carbonated water in Switzerland in the 16th century. However, the potential of artificial carbonation was not realized until experiments, such as JOSEPH PRIESTLEY's in 1767, brought it to public notice. In 1781, the world's first artificially produced mineral water was sold by THOMAS HENRY in Manchester, but on a very small scale. This may, in fact, have been the first carbonated soft drink, because he recommended to take it with lemon juice.

Commercialization on a somewhat larger scale was realized in Geneva in 1783, by PAUL and GOSSE, financed by SCHWEPPE. This was soon followed by JOSEPH HAWKINS, who started a new business in Philadelphia in 1808, producing "soda water" from artificial mineral water, sugar, and fruit juices. The next step took place in 1820 in Dresden, where F. A. A. STRUVE began the manufacture of soft drinks based on artificial mineral water and introduced the use of dyes and fruit acids. In 1839 J. W. WRIGHT produced a carbonated drink in Hamburg containing citric acid and lemon oil. The first Cola drink was produced in Atlanta by J. S. PEMBERTON in 1886, who experimented with a tonic wine in order to remove the alcohol and make it taste better. The result was Coca-Cola. He was soon followed by druggist C. BRADHAM who compounded Pepsi-Cola in 1893, based on extracts from kola nuts and vanilla, together with essential oils. It took until after World War II to gain worldwide acceptance of soft drinks, and they now constitute a significant part of our daily fluid intake. The cola beverages have developed into truly international drinks, and can be found virtually anywhere in the world. High-quality requirements and strict regulations have made possible reaching the mass production and public confidence that is today's standard.

4.1. Types of Beverages

Standards and regulations concerning soft drinks differ significantly from country to country. *Standards* specify those ingredients that must be present, usually at a minimum level, in order to be classified in certain categories, such as fruit juice drinks, sugar content, etc. *Regulations* are more concerned with additives and contaminants, and prescribe maximum levels. Many countries, e.g., United States, European Economic Community (EEC), use a "positive" list for those additives that may be used and none other. Other countries use a "negative" list wherein only those materials are listed that may not be used. Attempts are being made to simplify the complex system of food laws, e.g., Codex Alimentarius, and "harmonization" in the EEC. However, as long as there is no agreement on what constitutes "safe", it is unlikely that these differences in regulatory philosophy will disappear soon.

4.1.1. Still Drinks

Non-carbonated beverages were the first in recorded history, and they continue to represent the majority of drinks consumed today. In the United States about 25 % of the non-alcoholic beverages are carbonated, and in most other countries this is considerably lower (see Chap. 5). The non-carbonated drinks include water, coffee, tea, dairy beverages, and fruit juice products. Most non-carbonated beverages are produced in a ready-to-drink form, but in some markets, such as the EEC, fruit syrups are popular.

Production technology of non-carbonated drinks concerns mainly beverage stability, i.e., maintaining appearance and preventing microbiological contamination. Processing may include homogenizing dairy products or centrifuging fruit juices, but virtually always some form of thermal processing is required. The classical processes were retorting dairy products, and pasteurizing (tunnel or flash) juice products. Under these processing conditions, the containers could only be cans or bottles.

Aseptic packaging, originally developed for milk products in 1952 but also applied in the 1970s to fruit juices, has led to a tremendous number of better products and different containers, such as paper laminates. In this process, the product is pasteurized at high temperature for a short time (HTST), and aseptically transferred to a container that has been chemically sterilized with hydrogen peroxide. The worldwide growth in this type of product is expected to be between

8 – 10 %/a, mainly based on economic advantage. However, these products also often have a quality advantage because the thermal processing in this case does not affect flavor and color as much as retorting or hot packing does [109].

Most still drinks are *fruit flavored* and, in fact, contain fruit juice. The juice content varies from 100 % for pure juices, to 30 – 50 % for nectars, and to 10 % for fruit juice drinks. Other ingredients are sweeteners, acidulants (mainly citric acid), food color, flavoring, and ascorbic acid for vitamin C enrichment or as an antioxidant. *Nonfruit drinks* include protein-based beverages, such as drinking yoghurt, flavored milk, and soy beverages. Finally, there are coffee- and tea-based beverages, predominantly found in the Far East.

4.1.2. Carbonated Beverages

Standards for carbonated beverages differ significantly from country to country, but in many instances at least three categories can be identified:

1) *Fruit Juice Beverages.* This type of soft drink generally derives most of the flavor and appearance from fruit juice. The minimum juice requirement for this classification is regulated, and depends on the country and the type of fruit. For orange drinks it is, in most cases, at least 10 %; for lemon, typically about 5 %. These products usually can only be flavored with natural essential oils or extracts (see Section 4.2). Use of coloring is often prohibited or limited to natural products. In many countries use of preservatives is also prohibited in this category, and therefore tunnel pasteurization is usually applied to the bottled or canned beverage.
2) *Beverages with Natural Flavor.* This category can be separated into groups of *cloudy beverages* and *clear beverages.* In Europe the names "limonade" and "soda" are used, but are not always defined exactly the same from country to country. On a worldwide basis, this group represents the largest volume of carbonated beverages because it includes colas and lemon-lime beverages. The *colas* are the only truly international beverages because the major brands are marketed with virtually the same quality in about 150 countries; minor variations are the result of regulatory differences. Several countries have standards for cola drinks, requiring the presence of extracts (e.g., from cola nut), natural flavor, caramel color, and exclusively allowing caffeine and phosphoric acid. Tonic is also in the clear category, with quinine or other bitter substances added according to local regulations. The *cloudy group* contains orange flavored beverages, which in many countries is the second or third largest flavor category. The cloudy appearance may be due to relatively low levels of juice or to emulsions based on orange oil and emulsifiers as permitted by local regulations.
3) *Beverages with Artificial Flavor.* This is a catch-all category where generally more additives are allowed than in the above two groups. This is often the group where *diet beverages*, based on intense sweeteners, are found. The situation in the United States is somewhat different because the soft drink standards cover only carbonated beverages based on nutritive sweeteners and, therefore, diet beverages are nonstandardized, thus requiring declaration of ingredients and other information.

4.2. Flavoring Materials and Concentrates

Flavor is one of the main properties of beverages and is often the distinguishing characteristic between brands. The industry uses natural as well as synthetic flavoring materials and these are usually incorporated in some convenient form of "concentrate" which makes it possible to add flavoring to the beverage in a controlled fashion.

4.2.1. Natural Flavoring Materials

Aromatic vegetable materials, such as fruits, flowers, roots, seeds, and bark, are the most common resource for natural flavors. In beverages the most popular flavors are derived from essential oils. Odoriferous oils have been known throughout history, but only early in the sixteenth century was distillation used to isolate

such oils. In fact, in the search for the "Quinta essentia" or the active principle of drugs, the volatile oil was discovered. Distillation did not yield the most effective part of the drug, but instead gave the volatile oil that represented the odor of the drug. The name *essential oil* was maintained, however.

Essential oils are produced by cold-pressing, distillation, or extraction. Citrus oils are the most popular in the beverage industry, and these are generally produced by cold-pressing or by scraping the peel, e.g., orange, lemon, and grapefruit. Lime oil is typically produced by steam distillation, but some cold-pressed is also done. The yield of citrus oils is about 3 – 7 kg/t. The citrus oils consist of > 90 % terpenes, empirical formula $C_{10}H_{16}$, and low levels of oxygenated compounds, such as octanal, citral, terpineol, etc. The terpenes contribute little flavor and are very slightly soluble in water. For these reasons, and especially in clear beverages, the terpenes are often partially or completely removed. The most popular method to remove them is distillation. In addition extraction is used and, to a small extent, chromatography.

Most other essential oils used in beverages are produced by steam distillation, e.g., ginger, cinnamon, anise, etc. Yield varies widely, such as 0.2 % for cinnamon and 17 % for clove.

Oils produced by extraction are not essential oils according to definition because they also contain nonvolatile ingredients. Examples are some of the floral oils, popular in fragrances, and used at low levels in some beverage flavors. Spice extracts, such as ginger root for ginger ale, are more popular, and in this case the extract contains not only the essential oil but also the pungent character of the root. Citrus extracts are also widely used, particularly for clear beverages. The citrus peel or the oil is extracted with alcohol and water in order to obtain the "soluble essence". In the case of peel extraction, this is usually followed by distillation to separate the terpenes, which are poorly soluble in the distillate [110–112].

Many other extracts are used for flavoring of beverages, and some of the best-known examples are vanilla bean extract and cola nut extract, used in cola beverages worldwide. Another example is the extract of guarana seed, which contains caffeine, and is used in Brazil. The most common solvents for such flavor extracts are ethanol and propylene glycol.

4.2.2. Synthetic Flavoring Materials

The beverage industry applies predominantly natural flavoring ingredients, but some synthetic materials are also used, alone or in combination with natural ones. Synthetic material is found mainly in noncitrus flavors, such as strawberry, cherry, etc.

Most of the synthetic flavoring compounds occur also in nature, and only a few are strictly unique. An example of a natural flavor is vanillin [*121-33-5*] (4-hydroxy-3-methoxybenzaldehyde), which occurs in the vanilla bean. Synthetic vanillin can be produced from lignin, a byproduct from paper manufacture, or from eugenol, a natural constituent of clove oil. An example of a manufactured or artificial flavoring compound is ethyl vanillin [*121-32-4*] (3-ethoxy-4-hydroxybenzaldehyde).

The largest volume flavoring materials are simple esters, such as ethyl butyrate and amyl acetate, as well as aldehydes, such as benzaldehyde and vanillin.

4.2.3. Flavoring Concentrates

Most flavoring ingredients, with or without other additives, are used in a conveniently diluted form in order to ensure homogeneous mixing with the syrup or beverage. In Europe, where fruit juice-based beverages are quite common, a one component "Grundstoff" based on concentrated fruit juices together with flavoring extracts or oils is often used. Preparation of the beverage only requires addition of sugar and water to such a concentrate. The juices are often specially treated in terms of pulp content, particle size, and pectin content in order to ensure a stable appearance of the beverage with the least amount of sediment. Such concentrates are usually homogenized at high pressure, particularly if essential oils are used, to stabilize the emulsion.

In the case of franchised beverages, the concentrates usually contain several components, some of them in dry form, but always containing all the ingredients except for water and sugar to

prepare a fixed amount of bottling syrup. Well-known examples are cola and lemon-lime beverages.

The most popular flavor concentrates, such as cola and orange, are in *emulsion* form because they are based on essential oils which need to be dispersed. The cola concentrates are to a large extent caramel-based emulsions [113], whereas most other flavors use gum acacia or modified starch, etc., as emulsifiers. In cloudy beverages without juice, other emulsifiers and stabilizers, e.g., glyceryl ester of wood rosin, brominated vegetable oil, sucrose acetate isobutyrate, are required in order to reduce and maintain the oil phase at a particle size of about 1 μm. With clear beverages, the concentrates are either a soluble essence, such as lemon-lime, or a solution of flavoring ingredients in suitable solvents, such as ethanol, propylene glycol, 2-propanol, etc.

Other important concentrate ingredients can be found in the list of additives that are allowed in soft drinks for each country. The most popular *acidulants* include orthophosphoric acid, used strictly for cola beverages, citric acid and malic acid for fruit drinks, and tartaric acid, used almost exclusively for grape beverages. Among *food colors,* the most important one for beverages is undoubtedly caramel, a polymer prepared by heating dextrose in the presence of ammonium sulfite. The most important artificial color is Sunset Yellow (C.I. 15985), followed by Tartrazine (C.I. 19140). The most controversial colors are found among the reds where regulatory opinions differ significantly. The well-known red colors are: Amaranth (C.I. 16185), Carmoisine (C.I. 14720), and Allura Red (C.I. 16035).

Preservatives are needed to retard growth of microorganisms. Benzoic acid is the most widely used one, followed by sorbic acid, and to a much lesser extent sulfites. *Alkaloids* are another important class of additives, and these are used to modify taste and to add refreshment. Caffeine is used in cola beverages at about 100 mg/L, and also in some other beverages. Quinine is only used in tonics. Additives also include antioxidants, such as ascorbic acid, buffers, such as sodium citrate, and several others for special applications [114].

4.3. Beverage Production

The technology involved in preparing beverages is mainly found in equipment engineering, such as high-speed filling lines, aseptic fillers, etc., and is beyond the scope of this review.

Most *non-carbonated beverages* are prepared by simple mixing of the ingredients followed by pasteurization either as is or within the container. Dairy products usually require more processing, such as homogenizing, and are often sterilized, in a retort for instance.

In the production of *carbonated drinks* five separate activities can be distinguished: 1) water treatment, 2) syrup preparation, 3) carbonating and filling, 4) wastewater treatment, 5) quality control.

4.3.1. Water Treatment [115]

The type and amount of impurities in water vary considerably and depend largely on the source. Water treatment removes impurities and makes it suitable for beverage use. Common *impurities* include:

1) turbidity and sediment due to suspended insoluble matter
2) color caused by organic matter
3) microbiological organisms
4) salts which raise the alkalinity and may affect taste
5) mineral acids
6) hydrogen sulfide.

Most water treatment systems (see Fig. 13) involve four basic *processes:* alkalinity reduction, chlorination, coagulation, and clarification. The *chemicals* required are: lime, chlorine, and ferrous sulfate. These are added in a reaction tank where most of the sludge settles. The clear overflow from this tank is filtered through sand or diatomite, and a carbon purifier removes chlorine and trihalomethanes. For water containing high-organic matter, ozone is used instead of chlorine, in order to prevent formation of additional trihalomethanes. In cases where dissolved solids are extremely high and sodium content must be reduced, three alternatives to chemical treatment are: reverse osmosis, electrodialysis, and ion exchange.

Figure 13. Water treatment plant
a) Reaction tank; b) Sand filter; c) Carbon purifier; d) Polisher∗ Courtesy PepsiCo, Inc.

4.3.2. Syrup Preparation

Sucrose [*57-50-1*] , mainly in granulated form, is the most common sweetener in carbonated beverages (→ Sugar). The beverage industry uses cane as well as beet sugar of high purity. Sucrose is also sold as syrup, the so-called liquid sugar, which is popular in the United States and Europe. Sugar syrup is also supplied partially *inverted*, i.e., the sucrose is converted to dextrose and fructose in order to improve stability and allow a higher solids content. Inversion can be accomplished by heating with mineral acid, by ion exchange, or by use of invertase. A relatively new sweetener is *high-fructose corn syrup* which is prepared by enzymatic conversion of corn starch. In this syrup, about 55 % of the solids is fructose, about 42 % dextrose, and the remainder higher saccharides. In the United States this sweetener has already replaced more than 50 % of the sucrose that is used in soft drinks.

When granulated sugar is used, the bottler prepares a syrup (melting), which usually requires at least filtration, and often treatment with activated carbon to remove color or odor. The syrup room contains various stainless steel mixing tanks where the syrup is prepared and held until it can be bottled. The sugar syrup is measured into a tank along with the flavor concentrate and other additives. After the required quality control steps, the bottling syrup is ready for use.

In *low-calorie drinks,* the nutritive sweetener is replaced by intense sweeteners, such as saccharin, cyclamate, or aspartame (→ Sweeteners). The use of these sweeteners is restricted through food regulations and differs from country to country. Blends of intense sweeteners are preferred because of synergism and also undesirable taste can be minimized. The sweeteners are used in a soluble form, such as sodium or calcium salts, and a "syrup" is prepared similar to a regular bottling syrup. Sugar sweetened drinks normally contain about 10 % sucrose, but in low-calorie drinks, the amount of sweetener is very low, e.g., 0.04 – 0.05 % for saccharin and aspartame, or 0.2 % for cyclamate.

4.3.3. Carbonation and Filling

The final stage of soft drink preparation consists of mixing bottling syrup and treated water in a certain ratio, carbonating under pressure, and filling into bottles or cans.

The traditional method was to chill syrup and water separately, then "throw" an accurately measured quantity of syrup into the containers, and fill it with water that had been passed through the carbonator. After closing the container, the mixture was agitated to blend syrup and water. This technique (post-mix system) is still applied in low-speed lines and in product with high-pulp content.

In high-speed lines, water and syrup are blended in the correct proportions, usually 5 : 1, either through an orifice (United States) or through metering pumps (Europe). The premix beverage is then cooled, carbonated, and filled. The carbonator is a pressurized vessel in which liquid and carbon dioxide are brought in intimate contact. Degree of carbonation is a function of temperature and pressure (solubility of carbon dioxide increases as the temperature of the liquid decreases). The solubility of carbon dioxide is adversely affected by the presence of dissolved air in water, and therefore deaerators are often employed, certainly in canning lines. Variations of the two basic carbonation methods, such as injection of liquid carbon dioxide, are also being used [116].

A typical bottling line layout is shown in Figure 14; however, this is a basic line, and not the most sophisticated, such as syrup batching by computer, continuous blending, etc. A high-speed line typically can fill 1200 – 1500 con-

tainers per minute depending on size and type of container. For further information see [116–120].

4.3.4. Wastewater Treatment

In bottling operations with returnable bottles, as much as 60 % of the incoming water may go to waste; with proper reclamation, this can be reduced to about 30 %. In operations with nonreturnable containers, the wastewater load is considerably smaller, and is generally less than 10 % of incoming water.

Wastewater treatment consists at least of neutralization and biological purification. The latter method is widely used to reduce dissolved organic matter, such as sugar, through breakdown by bacteria. Two broad types of equipment are trickling filters and activated sludge [121].

4.3.5. Quality Control

Manufacturing of soft drinks begins and ends with quality control. First there is quality control on all concentrate ingredients, such as essential oils, and then on the concentrate itself. Secondly, the beverage ingredients, such as sugar and water, are checked on chemical and physical parameters and on microbiological condition. Finally, beverage samples are removed from the line periodically and checked to ascertain whether they are within specification. Tests may include carbonation, solids, titratable acidity, pH, color, and taste. In addition microbiological checks are performed. Electronic as well as visual inspections are made during filling on containers and fill height as well as on net content. In-line quality monitoring is also possible electronically, e.g., densitometer for solids, infrared absorption for carbon dioxide [118], [119].

5. Economic Aspects

From 1979 to 1983, nonalcoholic beverages recorded continuous growth in both consumption and monetary value in markets of the United States and Europe. The estimated retail volume of nonalcoholic beverages consumed in the United States over this 5-year period is noted in Table 7. In 1983 about 40.4×10^9 L of drinks and juices, and about 2.6×10^9 L of bottled waters were consumed (Table 7) [122]. The retail dollar value of the United States nonalcoholic beverage market in 1983 amounted to: soft drinks ($\$26.1\times10^9$), fruit juices and drinks ($\$7.8\times10^9$), drink mixes ($\$1.7\times10^9$), and bottled waters ($\$0.7\times10^9$).

The ten major companies and their market share of the soft drink, bottled water, and juice and fruit drink segments of the nonalcoholic beverage market are noted in Table 8 for the United States. The fastest growing areas of the soft drink industry are diet and caffeine-free beverages. Diet soft drinks account for about 18 % of the market and, in terms of flavors, cola leads with 63 % of the sales followed by lemon-lime with 14 %. Caffeine-free has become a major advertising issue, and some soft drink manufacturers enthusiastically proclaim that their products contain “no caffeine”.

5.1. Fruit Juices

The fruit juice market is depicted in Table 9. As noted orange juice is the overwhelming favorite of the American consumer with about 62 % market share. Frozen concentrated orange juice is the predominant product, but chilled orange juice has shown spectacular gains – consumption of 772×10^6 L in 1978 to over 1306×10^6 L in 1983 (represents sales of $\$542.5\times10^6$ to $\$1.1\times10^9$). Grapefruit juice is preferred after

Table 7. Estimated retail sales of single-strength nonalcoholic drinks and juices, $\times 10^6$ L [122]

Year	Packaged soft drinks (carbonated & noncarbonated)	Powdered soft drink mixes	Fruit flavored drinks	Juices (100 %)		Total all nonalcoholic drinks and juices
				Citrus juices	Other juices	
1 979	23 942	4 197	1 849	3 077	1 284	34 350

Schweppes USA	0.070	Gatorade	0.097	Black Mountain Spring	0.010

orange juice (7.2 % market share). It has not shown the spectacular growth demonstrated by orange juice because 70 % of consumers surveyed found the taste of grapefruit juice too tart for their liking.

Table 9. 1983 Fruit juice market for the United States [124]

Commodity	$\$\times 10^6$	% Market share
Orange juice	3842.3	62.1
Apple juice and cider	1094.0	17.7
Grapefruit juice	442.4	7.2
Grape juice	292.5	4.7
Pineapple juice	142.5	2.3
Prune juice	119.4	1.9
Blended fruit juice	94.0	1.5
Lemon and lime juice	92.8	1.5
Fruit nectars	65.9	1.1

The apple juice and cider segment (about 18 % market share) of the juice industry has been growing at a rate of about 20 % annually in recent years, with a jump of about 96 % in liters sold between 1978 and 1983, and a 169 % gain in dollars. The other fruit juices (grape, pineapple, blended, prune, lemon-lime, and nectar) collectively comprise a modest 11 % of the juice market. For the 1978 – 83 period, grape juice and pineapple juice showed retail gains of 13.5 and 11.9 %, respectively. Blended 100 % fruit juice ranks about seventh in the total fruit juice market but is increasing in market share; from 1978 – 1983 blended juice showed a 140 % volume increase and a 248 % dollar increase. Traditional blends are orange-grapefruit, pineapple-grapefruit, apple-grape, and applebery, but many other diverse blends are entering the market. The lemon-lime juice category remained stable, whereas prune juice and fruit nectars dropped more than 12 % and 18 %, respectively, during 1978 – 1983.

5.2. Carbonated Soft Drinks

Figure 15 compares the history of soft drink production in the United States with the rest of the world. In 1982, an estimated 16.8 $\times 10^9$ cases were manufactured throughout the world [125]. Of this, almost 37 % was produced and consumed in the United States.

5.2.1. United States Market

The United States continues to be a unique, evolutionary, and often revolutionary soft drink market. It is here where cola beverages were first discovered (Table 10), and where diet beverages became a major market segment. In 1949, the United States manufactured just over 1×10^6 cases (8.52 L) valued at \$760000. In 1982, 4.07×10^9 cases were manufactured valued at $\$21.2\times10^9$ (wholesale). This growth is illustrated in Figure 16.

The extraordinary growth of carbonated soft drink consumption has taken place at the expense of other beverages (Fig. 17). In 1962, carbonated soft drinks accounted for 9.2 % of per capita beverage consumption. In 1982, almost 22 % of all liquid consumption in the United States was soft drinks. Over this period (1962 – 1982), the percentage of coffee, milk, and water consumed per capita fell dramatically because of the increase in soft drink consumption as well as increases in beer, wine, bottled water, and powdered beverage consumption.

A major factor in the extraordinary growth of soft drink consumption has been cola beverages, first introduced over 100 years ago. From 1966 to 1982, colas consistently accounted for 62 – 63 % of total soft drink production, lemon – lime beverages 11 – 12 %, and root beers, another unique United States beverage, about 5 – 5.5 % (Fig. 18) [125–127]. During this same period, the acceptance of pepper beverages has steadily increased to about 7.5 % of total production. Orange consumption fell slightly, dropping from 9.5 % in 1966 to 7.6 % in 1982, as did the production of other flavored soft drinks, which accounted for 5.1 % of 1982 production.

In order to maintain growth, the United States marketplace has become much more segmented, particularly in the cola category, as evidenced

Figure 16. Growth of United States soft drink industry [125]

Figure 17. Per capita consumption of various beverages by United States consumers [125–127]

in Table 10. Figure 19 shows the extraordinary growth and acceptance of diet beverages. The growth of diet beverages can be correlated especially to the entry of major manufacturers into the diet cola market. In 1983, diet colas accounted for approximately 67 % of the total diet market. The cola market has been further segmented with the introduction of caffeine-free colas, and their impact has been significant. In 1983, regular caffeine-free colas accounted for 6.1 % of the cola market, and diet caffeine-free colas for 5.4 %.

The prime movers and benefactors of the United States consumers' love affair with colas

Figure 18. United States soft drink production by flavor type [125–127]

Figure 19. Share of United States diet beverages sold per annum – based on sales of bottled and canned beverages, and including all flavor types

has been the major cola manufacturers, as shown in Figure 20. From 1966 to 1982, the market was dominated by Coca-Cola and Pepsi-Cola companies, accounting for 34.5 and 25.0 % respectively, of 1982 production, followed by Seven-Up, Royal Crown, and Dr. Pepper, which accounted for 6.9, 4.3, and 6.4 %, respectively.

5.2.2. International Markets

In past years, international sales of carbonated soft drinks has grown in a manner similar to the United States, although volume has shown some instability because of tensions from worldwide economic conditions. In 1982, 10.6×10^9 cases of carbonated soft drinks were sold throughout

Figure 20. United States production of carbonated soft drinks by major manufacturers [125–127].

the world (Fig. 21). Over half this production was in those countries listed in Table 11 [128].

Table 11. Estimated market size of selected major international markets [128]

Country	1982 $\times 10^6$ cases *
Argentina	173.2
Australia	174.5
Belgium	103.9
Brazil	500.2
Canada	293.9
Federal Republic of Germany	851.2
France	212.4
Italy	284.5
Japan	480.8
Mexico	971.4
Netherlands	156.4
South Africa	176.1
Spain	322.1
United Kingdom	352.2
Venezuela	195.7
Total	5248.5

* 1 Case = 5.68 L

Like the United States, the international soft drink market also supports much cola beverage consumption, but to a much lesser extent (Fig. 21). In 1982, cola beverage production accounted for 37.1 % of production, up from 31.3 % in 1971. Diet colas, as well as other diet soft drinks, played an insignificant role in worldwide soft drink production in 1982, accounting for only 0.5 % of total production. Further segmentation into caffeine-free colas is essentially nonexistent in international markets, with the primary exception of Canada.

Although cola beverages are not dominant internationally, the primary United States cola manufacturers accounted for nearly 45 % of all international sales in 1982 (Fig. 22).

1. Introduction

Biological control is the action of natural enemies in maintaining another organism's population density at a lower level than would otherwise occur. In this article, however, the traditional definition has been expanded to include chemicals that duplicate or mimic natural ones. The major effort in biological control has been focused on the suppression of populations of pest insects. However, biological control of weeds and plant pathogens is a very active area of research. Biological control techniques also have been used successfully to suppress populations of animals other than insects. Biological control is a global endeavor; specialists in this discipline have developed a worldwide organization, *International Organization for Biological Control of Noxious Animals and Plants* (IOBC). More information on IOBC may be obtained by contacting: Secretary-General, G. Mathys, 1, rue Le Nôtre, F-75016 Paris.

Classical biological control involves: (1) discovery, (2) importation, (3) release, and (4) establishment of exotic species of natural enemies. Most pest insects, especially in the United States, are pests because they were introduced accidentally, or on purpose, leaving their complex of natural enemies behind. For example, several thousand species of insects have been introduced into the United States in attempts to control a few species of insect pests.

Applied biological control is sometimes implemented when a natural enemy does not become established. This involves: (1) augmentation and (2) conservation. Augmentation is the manipulation of a natural enemy, and conservation is the manipulation of the environment, both to enhance the impact of the natural enemy on the pest population. Examples of augmentation are colonization and periodic release of natural enemies and improvement of the efficiency of a natural enemy through selection. Conservation involves, e.g., using different cultural practices that serve to protect the natural enemy in the environment.

Natural enemies are: (1) parasitoids, (2) predators, and (3) pathogens. A parasitoid (parasite) is an insect that lays an egg on, or in, a single host insect. The parasitoid develops internally, killing the host. Predators are free-living organisms that kill and consume their prey im-

mediately or within a short period of time. Predatory insects kill and consume more than one host or prey during their development. Predators are found in all major orders of insects. Parasitoids and predators are referred to as entomophagous insects. Pathogens are microorganisms that cause diseases in insects. Most insect diseases are caused by bacteria, fungi, protozoa, microspora, and viruses. These organisms are collectively referred to as entomopathogens. The phylum Nematoda consists of a group of round worms called nematodes. Some nematodes are natural enemies of insects; some nematodes behave like parasitoids, whereas others behave like insect pathogens. These nematodes are referred to as entomophagous nematodes.

In the biological control of weeds, natural enemies usually are phytophagous insects and microorganisms that cause diseases of plants. Natural enemies of plant pathogens include predacious insects that feed on the fruiting bodies of pathogenic fungi and microorganisms that are parasitic on other microorganisms.

History. Several references are made to early examples of natural enemies being used to control pests. For example, in the year 1200, Chinese citrus growers purchased nests of the predacious ant, *Oecophylla smaragdina*, and placed them in citrus trees to control a caterpillar, *Tessarotoma papillosa.* Many other examples of successful biological control are recorded, including the introduction to California of the vedalia beetle, *Rodolia cardinalis,* in 1888 to control the cottony cushion scale, *Icerya purchasi* [24]. This project saved the citrus industry of California and was the impetus for additional biological control projects against insect pests.

Widespread adoption of host-specific biological control techniques was slowed by the development of relatively inexpensive synthetic chemical insecticides that had a broad spectrum of insect targets. These compounds were envisioned to be the permanent solution for problems with insect pests.

The public concern for environmental conservation that has surfaced over the past 25 years has again stimulated interest in, and financial support for, biological control programs. During this time, intensive research has been conducted in the area of insect biochemistry; specifically, insect hormones and semiochemicals. *Hormones* are chemicals that are produced in certain body tissues, are transported within the body by the circulatory system, and elicit a response in another part of the body (→ Hormones). *Semiochemicals* also are produced within the body but are emitted externally to elicit a response. The hormones of interest in biological control are those that regulate growth and molting of the insect; the semiochemicals are those that elicit a sexual response or attract an insect to a point source. The use of biochemicals, such as hormones and semiochemicals, is not a method of biological control in the strict sense. These chemicals, plus male-sterile techniques, host plant resistance, and genetic manipulation, are merely other biological methods used to control insects (see Chap. 5).

Entomologists have determined the economic threshold or economic injury levels for many important insect pests on many agricultural crops. These data allow a grower to determine how many insects can be tolerated by a crop before control is economically feasible. In developing this information, researchers have become aware that complete control or elimination of a pest is not necessary and that measures less drastic than a chemical insecticide, such as biological control, can be effective in protecting crops. This has brought about the present-day approach to pest control known as *integrated pest management* where a holistic approach is taken in suppressing pest populations. Briefly, this involves the assessment of a pest problem and the judicious use of two or more methods of control (parasitoids, chemical insecticides, predators, pathogens, hormones, semiochemicals, plant resistance, and cultural practices) in a compatible system that will reduce the pest population to an acceptable level. At all times, attention must be paid to using sound ecological principles so as not to disturb the beneficial regulatory factors present in nature.

1.1. Entomophagous Insects

An ecosystem has a relationship between a host (plant, animal, or commodity), insects feeding on the host, and organisms feeding on the insects. An example of this relationship is illustrated in Figure 1.

Figure 1. Example of an ecosystem

2. Biological Control of Insects

2.0.1. Parasitoids

The great majority of parasitoids are found in the insect orders of Strepsiptera, Coleoptera, Lepidoptera, Hymenoptera, and Diptera, with by far the most being classified as Hymenoptera and Diptera. To be successful, a parasitoid should have the following attributes: (1) good searching ability, (2) high biotic potential, and (3) ability to operate effectively throughout the entire geographic range of its host. A typical female parasitoid selects a suitable host, deposits a single egg either on or within it, and leaves in search of other suitable hosts. The parasitoid egg hatches and develops within the host insect. During the early stages of development, the parasitoid does not greatly disturb the host insect. Later, as the parasitoid reaches maturity, the host insect becomes immobile, at which time the parasitoid will leave the host's body and pupate. Shortly afterward, the host usually dies.

There are many variations in the parasitoids as to developmental stage of host most desirable for parasitization. Some parasitoids prefer young larvae, some older larvae, and some even the pupal stage. Other parasitoids parasitize only insect eggs.

An example of a "generalized" hymenopteran parasitoid is *Bathyplectes curculionis*, imported from Italy to assist in controlling the alfalfa weevil, *Hypera postica.* Some parasitoids deposit several eggs in a host insect. These eggs hatch, and then at maturity several hymenopterous pupae are seen attached to the surface of the host insect. *Trichogramma* spp. are well-known as egg parasitoids. The females of these minute insects deposit one or more eggs within the eggs of different species of insects (Fig. 2). There is sufficient nutritive material present within the egg to support the development of this small parasitoid.

Figure 2. *Trichogramma* wasp preparing to oviposit in an insect egg
∗ Courtesy of Gerald R. Carner, Clemson University

Some Hymenoptera possess a biological modification known as polyembryony, the development of several individuals from a single egg. In this situation, an adult female, e.g., *Macrocentrus grandii* (Fig. 3), a parasitoid of the European corn borer, *Ostrinia nubilalis*, deposits a single egg in a second-stage corn borer larva. The primary embryonic germ divides by fission to form two secondary germs which split into a variable number of morulae, each of which develops into an embryo.

Dipterous parasitoids exhibiting a general developmental cycle are represented by *Winthemia quadripustulata*, a parasitoid of the armyworm, *Psuedaletia punctata.* The adult female deposits an egg directly behind the head capsule of a suitable host. The parasitoid larva hatches from the egg and chews its way into the body tissue of the host, develops to a mature larva, chews its way out of the larva, and pupates. A dipterous parasitoid with a different biology is *Blepharipa*

prantensis, a parasitoid of the gypsy moth, *Lymantria dispar.* The female parasitoid deposits its egg on the foliage where gypsy moth larvae will feed. The parasitoid is fully developed within the egg, and the slight pressure exerted by the mandibles during feeding causes the parasitoid to break out of the egg shell.

Figure 3. Adult female *Macrocentrus grandii,* parasitoid of the European corn borer, *Ostrinia nubilalis*

Bonnetia comta (Fig. 4), a parasitoid of several cutworms, deposits eggs on host fecal material. These eggs immediately hatch, and the neonates or planidia rest on their freshly cast egg chorion waiting for their host to move.

Figure 4. Adult female, *Bonnetia comta,* parasitoid of several cutworm larvae

Still another unique modification is the larvipositing phenomenon exhibited by *Lydella thompsoni*, a parasitoid of *O. nubilalis.* The adult female searches for entrance holes that tunneling larvae of the European corn borer have made and deposits live larvae in the fecal material voided by the feeding corn borer larva. The parasitoid larvae actively search for and enter the host by chewing through the insect cuticle.

These few examples of parasitoids give only a brief overview of the fascinating and sometimes complex biology of insect parasitoids.

2.0.2. Insect Predators

Predacious insects differ from parasitoids in that a predator consumes several insect forms during its life cycle. Also, in many instances, both the immature and adult stages of the insect are active predators. Most orders of insects contain at least one family of predators.

The scope of this article does not allow a treatment of examples from all orders of insects; only a few predators that a home gardener or general naturalist would most likely recognize are described. The order Coleoptera (beetles) contains by far the greatest number of predacious species. The ubiquitous lady beetle (Fig. 5) has been observed by many. The female lady beetle lays its eggs in clusters in a habitat near a food source. The newly hatched larva is a voracious feeder, consuming insect eggs, aphids, and small immature insects. The adult lady beetle also is predacious, devouring a general variety of prey. However, some of these coccinelid beetles are very specific in their prey, i.e., the vedalia beetle, *Rodolia cardinalis*, feeds only on the cottony cushion scale, *Icerya purchasi.* The ground beetles are another group of ubiquitous Coleoptera that are general predators, feeding on insect eggs, caterpillars, and even the adult moths of some species. There also are many predacious aquatic beetles that prey on almost any aquatic form of life that can be captured.

Figure 5. Adult lady beetle, *Coleomegilla maculata*

Dragonflies and damselflies (order Odonata) frequent country ponds in the summer. The immature forms of these insects are aquatic and are predators of pond life. The adults capture their prey in flight. Depending on the size of the predators, the prey ranges from mosquitoes to adults of the orders Lepidoptera and Hymenoptera.

Another common predator found near water is the robber fly (order Diptera). The larvae feed on pest insects in the soil, whereas the adults capture flying insects in flight. Their prey consists mainly of mosquitoes and midges that are readily found in an aquatic environment. Syrphid larvae, also in the order Diptera, feed on aphids.

Most members of the order Neuroptera are predators. A representative is the green lacewing. The larvae of this insect feed on aphids, mealybugs, thrips, and other small insects. These larvae also are known to prey on the eggs of several lepidopterans. The adult lacewings prey on aphids and mealybugs if they feed on insects at all.

The praying mantid is predacious in both the immature and adult stages. These insects prey on almost any insect that they can overcome. They frequent flowers and capture insects visiting the flowers for nectar. The Chinese mantid, *Tenodera aridifolia sinensis,* is frequently made available commercially for the home gardener.

2.1. Other Predators

Insects are a main ingredient in diets of several birds, rodents, fish, amphibians, reptiles, and arachnids. For example, several birds, including the downy woodpecker, crow, robin, red-winged blackbird, purple grackle, chickadee, starling, and ring-necked pheasant, are known predators of the European corn borer [25].

2.2. Entomopathogens

Insect pathogens (entomopathogens) are microorganisms that cause diseases in insects. These pathogens can cause diseases in beneficial insects as well as pest insects. In this article, only diseases of pest insects will be addressed.

2.2.1. Bacteria

Entomopathogenic bacteria can be divided into three groups – those that fit the description of classical biological control (see Chap. 2), those that fit the description of applied biological control, and those that fit into either group. Regardless of the category in which these bacteria are classified, they have one thing in common, they can be grown in an insect and/or in a bacteriological medium. The most prominent bacteria in biological control are in the genus *Bacillus*, the group of gram-positive, mobile, spore-forming rods.

Bacillus thuringiensis is the most widely known and researched bacterium within this group and is differentiated from other spore-forming bacilli by the presence of a parasporal body that is formed within the sporangium during sporogenesis. The parasporal body is a high-molecular-mass protein crystal that is referred to as crystalline protein, δ-endotoxin, as well as a parasporal body. This protein moiety possesses some of the insecticidal properties of the bacterium [26]. Certain subspecies of *B. thuringiensis* under specific growing conditions produce several other toxins with insecticidal activity: α-exotoxin, β-exotoxin, and γ-exotoxin. The δ-endotoxin, however, is the most important toxin relative to insecticidal activity and thus is the one most studied.

The δ-endotoxin is produced commercially in submerged culture under the conditions described in the patent [27]. Fermentation medium is crucial to successful production. It primarily contains an energy source (carbohydrate) and a nitrogen source. Common sources of carbohydrate are hydrolyzed corn products, starch, dextrose, and molasses. Sources of nitrogen are fishmeals, cottonseed flour, corn steep liquor, soybeans, autolyzed yeast, and casein. Trace minerals, namely Mg^{2+}, Mn^{2+}, Fe^{2+}, Zn^{2+}, and Ca^{2+}, are usually added to the medium.

Bacillus thuringiensis is primarily a pathogen of lepidopterans. A general infection cycle is illustrated in Figure 6. To elicit its effect, the crystalline protein must be consumed by a susceptible insect larva. The protein crystal is actually a protoxin that is hydrolyzed by enzymes in the gut of susceptible insects, releasing the pure toxin. The toxin causes paralysis of the gut. The insect either starves to death, or the midgut epithelial cells are damaged, allowing the gut contents, including *B. thuringiensis* spores, to enter the hemocoel. At this time, a general infection occurs.

Most Lepidoptera are susceptible to the δ-endotoxin, but there are basic differences in the

Figure 6. Infection cycle of the bacterium *Bacillus thuringiensis*

pathological responses of insects to this toxin. Researchers have divided lepidopterous larvae into four groups according to response [28]. The first group, designed Type I, shows a rapid general gut paralysis resulting in death 1 – 7 h after ingestion of the crystal toxin. Type II larvae are characterized by midgut paralysis a few minutes after ingestion of crystals and by cessation of feeding, but not by general paralysis. Type III larvae have to ingest both spores and crystals, do not exhibit either general or gut paralysis, but do stop feeding. Affected larvae enter a morbid state of varying duration with a fairly slow bacterial multiplication and finally, with a lethal infection. Type IV larvae are not susceptible to the crystal toxin or spores but are susceptible to the thermostable exotoxin(s).

Within these categories, the definitive response is dependent on the age of the insect. For example, the European corn borer is a Type III larva responding to a combination of spores and crystals. However, pure crystals are highly toxic to neonate larvae and moderately toxic to 6-d-old larvae. A combination of spores and crystals is necessary to cause maximum larval mortality [29].

Not only are the insects categorized relative to their response, but also isolates are divided into subspecies based on the antigenic properties of the flagella that are present during the vegetative stage of growth [30], [31]. Some subspecies are further divided by the serology of the crystalline protein [32]. With use of one or both of these techniques, > 20 subspecies of *B. thuringiensis* have been identified.

Insects susceptible to *B. thuringiensis* do not necessarily respond the same to all subspecies of *B. thuringiensis.* Likewise, a subspecies of *B. thuringiensis* does not have the same virulency to all susceptible insects. A bioassay technique is used to quantify the toxicity or potency of the many isolates of the several subspecies.

Bacillus thuringiensis subspecies *israelensis* was isolated from a mosquito breeding site in Israel [33]. The discovery of this subspecies provided researchers with an isolate with consistently high toxicity against larvae of mosquitoes and blackflies (order Diptera). All other subspecies are predominantly toxic for larvae of Lepidoptera. This subspecies also contains a parasporal crystal protein. However, this crystal is irregular in size and instead of a single crystal, there are 3 – 5 crystals. The pathology caused by subspecies *israelensis* is similar to that of other subspecies of *B. thuringiensis* in susceptible Lepidoptera. The pathology in black flies is most likely very similar. *Bacillus thuringiensis* subspecies *israelensis* is also produced by submerged culture.

β-Exotoxin [*23526-02-5*], the other toxin produced by *B. thuringiensis,* is being emphasized as an insecticide.

β-Exotoxin

β-Exotoxin is a nucleotide produced during the vegetative stage of bacterial growth [34]. It is composed of adenine, ribose, glucose, and allaric acid with a phosphate group. β-Exotoxin is heat stable and is produced by subspecies *thuringiensis, kenyae, morrisoni, tolworthi,* and *darmstadiensis* [35]. These subspecies produce different quantities of exotoxin, depending on the culture medium. Also, indications are that some subspecies produce more than one exotoxin. Commercial production of β-exotoxin is carried out under patent US 3758383 [36].

Bacillus popilliae causes a "milky disease" in some beetles in the family Scarabaeidae, but most noted in the Japanese beetle, *Popillia japonica. Bacillus popilliae* is eaten by the grub; the spore germinates and penetrates the gut wall. Once in the hemocoel, the bacterium readily multiplies (septicemia), giving the grub a whitish appearance visible through the cuticle, thus the name milky disease.

Bacillus popilliae readily develops in larvae of the beetle, but microbiological techniques have not been developed to induce *B. popilliae* to sporulate in vitro; thus, all production is carried out by inoculating Japanese beetle larvae and harvesting the infected larvae. This technique has a drawback because the Japanese beetle is not easily grown in the laboratory.

Bacillus sphaericus is a spore-forming rod that is readily found in nature. It has been isolated from mosquito larvae, and much research has been conducted on several strains of this bacterium that are insecticidal to several species of mosquitoes. *Bacillus sphaericus* does not produce a parasporal body or β-exotoxin as does *B. thuringiensis.* However, there is a proteinaceous toxin located in the spore coat. Susceptible mosquito larvae consume the spore and partly digest the spore wall, releasing a toxin. This toxin causes feeding inhibition, swelling of the midgut cells, body tremors, and then death. Death can occur as soon as 0.5 h after consumption of the spores. Like *B. thuringiensis, B. sphaericus* is produced in submerged culture.

2.2.2. Pathogens with Protozoal Characteristics

Microspora. The phylum Protozoa has been split into seven distinct phyla [37]. This phylum contains the order Microsporida, intercellular parasites found essentially in all orders of insects, with new species being described and host records being published frequently. Pathologically, microsporidia differ greatly from other disease-causing organisms in that they generally do not cause immediate death of the host. A microsporidian infection usually is chronic. There are no specific symptoms to describe insects infected with a microsporidium. The infected insect usually is lethargic, has reduced feeding, is small, has morphological deformities, and fails to molt or pupate.

Although microsporidia are widely distributed in the insect world, most microsporidia infect a single, or at most, a very few hosts. *Nosema pyrausta* is a microsporidium of this type and is a classical biological control agent. *Nosema pyrausta* predominantly infects larvae of the European corn borer, *Ostrinia nubilalis.* A schematic illustration of the relationship between *N. pyrausta* and *O. nubilalis* is presented in Figure 7. *Nosema pyrausta* has a life cycle typical of the order Microsporida. A corn borer larva eats a spore (the resting stage *N. pyrausta*); the spore extrudes its polar filament, injecting a sporoplasm into a midgut cell. Some development occurs in the midgut, whereas other sporoplasms migrate through the midgut into the hemocoel and eventually infect other tissues. In the European corn borer, infections predominantly take place in the Malpighian tubules and in the reproductive tissues of the female insect. At this point, two routes are possible for the microsporidium (both routes occur in all cases of infection). The infection can develop in the midgut, causing these cells and spores to slough into the lumen and pass from the body in the fecal material. The fecal material then becomes a reservoir of *N. pyrausta* spores available to infect other corn borer larvae feeding in the same plant. This is known as *horizontal transmission*, i.e., transmission within a generation. This route readily occurs in nature and is an effective means of disease transmission [38]. If the insect in which the reproductive tissues became infected was a female, the spores either are dis-

seminated within the developing insect egg and infect the embryo during development (transovarial transmission), or they are passed on the egg shell and are consumed by the larvae at eclosion (transovum transmission). Transovarial and transovum transmission are collectively known as *vertical transmission*, i.e., transmission to a subsequent generation. Horizontal and vertical transmission are two very effective means of transmitting and maintaining an organism within an ecosystem.

The impact of *N. pyrausta* occurs in several ways. If the infection is intense enough (a tremendous number of spores per insect larva), the infected insect will die. If the insect develops to the adult with this infection, the impact of *N. pyrausta* is elicited by a shortened life span, reduction in the number of eggs laid, and a reduction in the number of eggs hatching and developing to maturity.

Vairimorpha necatrix is a microsporidium that infects a great number of insects, all being phytophagous Lepidoptera. This microsporidium also can cause an acute pathology, resulting in death of the susceptible larvae within several hours, and is an example of an applied biological control agent. If a newly hatched or relatively early stage larva consumes an excessive number of spores, the midgut cells are damaged, allowing entry of the midgut contents into the hemocoel, and the larva dies from bacterial septicemia. If the larva does not die from septicemia, the spore enters the hemocoel, and an acute infection of the fat body occurs. This infection becomes very intense, and the host usually dies before pupation or during the pupal period. The European corn borer is not as susceptible to *V. necatrix* as are several larvae in the family Noctuidae (cutworms, armyworms, etc.), and a few insects develop to adults. However, because of the intense infections at this time, the production of offspring is unlikely. The acute pathology caused by *V. necatrix* makes it improbable that any horizontal or vertical transmission will occur. If transmission does occur, it is likely by an insect larva feeding on infected cadavers, by cannibalism, or by insects feeding on foliage contaminated by infected insects that ruptured after death (horizontal transmission) [39].

Apicomplexa. The gregarines and some coccidia with potential as biological control agents are representatives of this phylum. An infection usually occurs by consumption of spores. The development cycle involves schizogeny, which increases the number of spores tremendously, destroying tissues and depleting energy reserves. This cycle takes 1 – 6 weeks, depending on the specific organism. *Mattesia grandis,* a pathogen of the boll weevil, *Anthonomus grandis,* is an example of this group and contributes to overwintering mortality of this insect. *Mattesia trogodermae,* a pathogen of a stored-grain beetle, *Trogoderma glabrum,* has great potential for controlling these beetles in warehouses. Adult males can be contaminated with spores and can transmit these spores to females during copulation [40].

Commercial application of pathogens with protozoal characteristics is limited because these organisms must be produced in vivo, in their respective hosts.

2.2.3. Insect Viruses

There are two general types of insect viruses, the occluded and nonoccluded viruses. The *occluded*-type viruses are characterized by having the infective units, the virions, enclosed by a protein capsule (occlusion body). This is the most emphasized group relative to biological control and includes the nuclear polyhedrosis viruses (NPV), the cytoplasmic polyhedrosis viruses (CPV), the granulosis viruses (GV), and the entomopox viruses or insect pox viruses. The iridescent viruses, parvoviruses and picornaviruses are representatives of the *nonoccluded* viruses.

The occlusion body of an NPV is many-sided and encloses several virions. The virions are rod-shaped, and replication occurs within the cell nucleus. A generalized cycle, using a nuclear polyhedrosis virus, is illustrated in Figure 8. The inclusion bodies (occlusion bodies) are consumed by the insect and the proteinaceous capsule is hydrolyzed in the alkaline gut, releasing the virions. The virions enter the midgut cell nucleus, at which point they replicate and destroy the cell, or else the virions pass through the cell into the hemocoel and infect cell nuclei of other tissues, replicate, encapsulate, and rupture the

Figure 7. Infection cycles of the microsporidium *Nosema pyrausta*

cell. Insects infected with NPV exhibit sluggish retarded growth and a behavioral change characterized by moving to the top of a host plant where they die, and the integument usually ruptures. The primary tissues infected with a nuclear polyhedrosis virus are the midgut, tracheal matrix, fat body, and hypodermis. A viral infection in these tissues with eventual rupturing of the cells gives rise to a classical viral death where the internal organs have liquefied, and the cuticle of the insect is a mere "bag" of viral occlusion bodies. Once this "bag" breaks, the occlusion bodies contaminate the surface to which the insect was attached and become available for consumption by other susceptible insects.

Insects infected with a CPV display discoloration of the midgut (visible through the integument), experience retarded growth, and eventually die. The integument does not rupture. The shape of the occlusion body varies, and several virions, icosahedral in shape, are within each occlusion body. The infection occurs within the cytoplasm of the cell.

A GV infection is relatively nondescript but is generally characterized by retarded growth of the insect and a paling of color of the integument. In some infections, the occlusion bodies are passed into the hemolymph, giving a milky color. The occlusion bodies of this virus are formed within the cell nucleus and usually contain a single rod-shaped virion. Insects infected with a pox virus are sluggish and have an extended developmental stage. The occlusion bodies develop predominantly in the fat body, both in the nucleus and in the cytoplasm of the cell. The occlusion body contains many ovoid infective units.

Insect viruses were believed to be host specific (only infecting a single species of insect), but research has revealed that some nuclear polyhedrosis viruses will infect more than one species. For example, the nuclear polyhedrosis virus from the alfalfa looper, *Autographa californica,* infects several alternate hosts [41], including some from which a virus has never been isolated, i.e., the European corn borer and the black cutworm [42], [43]. This aspect of a wider host range for a virus increases the feasibility of using viruses in applied biological control. Insect viruses can be produced only in respective hosts.

2.2.4. Fungi

Most entomopathogenic fungi belong to the class Deuteromycetes (Fungi Imperfecti), with some very important entomopathogenic fungi in other classes. Insects infected with a fungus exhibit general lethargy, slowed growth, cessation of feeding, and changes in coloration of the integument. The difference between fungi and other pathogens is that the former do not have to be eaten by the insect to cause disease, but instead grow through the insect's skin.

A general infection cycle for fungi is illustrated with *Beauveria bassiana* as an example (Fig. 9). The resting stage or conidium comes in contact with the insect cuticle. The conidium germinates and enzymatic action partly digests the cuticle, allowing the hyphae to penetrate the

Figure 8. Infection cycle of a nuclear polyhedrosis virus

cuticle. The hyphae develop, forming a network of mycelia within the body cavity. Death usually occurs after this mycelial growth has spread throughout the body cavity. At this time, the mycelia grow out of the body, forming conidiophores and conidia. These formations are unique and definitive in some fungi. For example, *B. bassiana* conidia cover the infected insect, transforming it into a white covered mummy. This fungus is referred to as the white muscardine. *Metarrhizium anisopliae* turns an insect into a green-covered mummy and is called the green muscardine fungus. Both these fungi infect a wide range of insects. *Nomuraea rileyi* also coats insects with a green covering but is not as "fuzzy" as *M. anisopliae.* The conidia of these fungi become airborne and eventually infect other insects.

Some insects exhibit a typical behavior pattern once infected. Diptera (flies) infected with *Entomophthora musca* climb to the top of vegetation, wrap their legs around a grass stem, for example, and die; then mycelia grow on the external surface. A similar response occurs in grasshoppers infected with *Entomophaga grylli.* These fungi forcibly discharge the conidia from the conidiophores. Both these fungi are members of the class Zygomycetes. The class Oomycetes contains the species *Lagenidium giganteum,* a pathogen of several species of mosquitoes.

Entomopathogenic fungi are omnipresent; however, their effectiveness as a biological control agent is dependent on temperature, moisture, and wind. Each species has certain requirements relative to these environmental variables that must be met for the fungus to be effective. Fungi can be produced on submerged culture or on agar plates.

Figure 9. Infection cycle of the fungus, *Beauveria bassiana*

2.3. Nematodes

Nematodes (phylum Nematoda) are elongated cylindrical worms that are parasitic in animals or plants, or are free-living in soil or water. Nematodes are of importance in the biological control of insects. Several families of nematodes have members parasitic to insects. Nine families show potential as biological control agents [14]. In this article the families Mermithidae and Steinernematidae are be mentioned as examples of insect parasitic forms.

The **mermithids** have both aquatic and terrestrial species. *Romanomermis culicivorax* is an aquatic species that is parasitic to several

species of mosquitoes. *Romanomermis culicivorax* hatches from an egg and actively seeks a mosquito larva and penetrates the larval integument by use of a stylet and enzymatic secretions. The nematode completes its development within the insect hemocoel and then leaves the host by boring through the integument. At this time, the host usually dies. Once in the aquatic environment, the nematode develops to adulthood and mates. The female deposits its eggs to continue the cycle.

Mermis nigrescens, a representative of a terrestrial mermithid, is mainly a parasite of grasshoppers, but will occasionally parasitize other insects, including beetles. Adult *M. nigrescens* live in the soil. The female climbs vegetation, lays her eggs, and returns to the soil. An insect eats an egg. Once in the gut, the egg hatches, and the nematode penetrates the midgut, enters the hemocoel, develops within for several weeks, and then leaves the host (the host dies at this time); the nematode enters the soil and develops to adulthood. Mating may or may not occur. Reproduction can take place parthenogenetically.

The **steinernematids** are represented by *Neoaplectana carpocapsae,* which parasitizes terrestrial insects within several orders. Infective nematode larvae actively enter a host through the mouth, the anus, or through a spiracle, and proceed to the hemocoel, where they begin development. The steinernematids have a symbiotic relationship with a bacterium. As the *N. carpocapsae* larvae develop, a bacterium, *Achromobacter nematophilus,* is released through the anus. This bacterium creates a desirable environment in which *N. carpocapsae* develops. The nematodes develop to maturity and mate, and the female deposits her eggs. These eggs hatch, and the larvae develop to infective stage and then leave the host, ready to start the cycle again.

Nematodes exist in nature. However, some nematodes, including both the aforementioned ones, are produced commercially and, therefore, are available as applied biological control agents. Methods have been developed for in vitro production of nematodes. A high-protein source free from bacterial contamination is a necessity [14].

3. Biological Control of Weeds

The biological control of weeds theoretically involves the use of any organism that uses the weed as a food source or as a host. In general, most successful programs in biological control of weeds involve the use of phytophagous insects or insects that feed on these weeds. There are several programs throughout the world that have been successful in controlling weeds. For illustrative purposes, a few of the more prominent ones will be emphasized.

3.1. Phytophagous Insects

Control of the **prickly pear cactus** in Australia in the 1920s was one of the earliest successes. Larvae of the moth *Cactoblastis cactorum* were imported from Argentina and destroyed populations of this group of cacti. In the United States, these cacti have been substantially controlled by a cochineal insect, *Dactylopius opuntiae,* imported from Hawaii.

The **Klamath weed, Hypericum perforatum,** was introduced to northwestern North America in the early 1900s and has been successfully suppressed by two beetles, *Chrysolina hyperici* and *C. quadrigemina,* which were imported from Europe via Australia.

Musk thistle, a weed in range and pasture land in many areas, is host to a weevil, *Rhinocyllus conicus,* that lays its eggs in the seed head of the thistle. *Rhinocyllus conicus* was introduced into western Canada and into the United States (Montana, Nebraska, and more recently Iowa) and has a definite negative impact on this weed.

These three plants are examples of control of terrestrial weeds. Successful control of an aquatic plant, the alligator weed *Alternanthera philoxeroides,* has been demonstrated in inland waterways in Florida. Control has been obtained with a beetle, *Agasicles hygrophila,* and a moth larva, *Vogtia malloi.*

3.2. Plant Pathogens

The use of plant pathogens for control of weeds is a relatively new approach. Most of the emphasis has been with plant pathogenic fungi. Basic

research is performed under carefully controlled conditions to assure the specificity of pathogens. *Phytopthora palmivora* is a fungus that is specific for the **milkweed vine.** Some of these plant pathogenic fungi maintain themselves in the soil and thus are excellent biological control agents. *Alternaria cassiae* is a fungus that shows potential for control of **sicklepod.** Several other fungi are being extensively researched for biological control of weeds. This discipline will have a tremendous impact on weed control in the future.

3.3. Higher Animals

Tansy ragwort, *Senecio jacobaea,* is a biennial weed containing pyrrolizidine alkaloids. These alkaloids cause liver damage in livestock that consume these weeds. However, sheep are seemingly immune to this alkaloid. Therefore, they can graze this plant and keep it from producing seeds, thus reducing the plant population [44].

Biological control of weeds is a very active area of research. More and more phytophagous insects and plant pathogens are being evaluated as potential biological control agents. Once the basic research has been completed, several of these organisms will most likely be used to aid in suppression of weeds.

When selecting weedy plants as potential targets for biological control, one must be certain that the weed is classified as a weed in all areas of the country where it occurs. In some parts of a country, a certain plant might be a weed. However, in other locations, the plant might be beneficial as food source, habitat for wildlife, or for ground cover. The host range of phytophagous insects and plant pathogens also must be extensively researched to be absolutely sure that desirable plants that are closely related and might become an alternative host, do not exist in the country of introduction.

4. Biological Control of Plant Pathogens

Plant pathogens are a group of pests that cause tremendous loss of plant life every year and are primarily suppressed or controlled by chemical pesticides. However, there are biological control agents that use these microorganisms as sources of food or as hosts.

4.1. Macroorganisms

Fungi (smuts, rusts, and mildews) are food sources for several insects, but applied biocontrol of plant pathogens by insects has not been encouraging.

4.2. Microorganisms

The complex interrelationships between plant pathogens and microorganisms that have the potential of controlling them have been studied. Cucumber powdery mildew has been experimentally controlled by application of the fungus *Ampelomyces quisqualis* [45]. *Ampelomyces quisqualis* is a hyperparasite that obtains nutrients from the mildew. The fungus *Trichoderma harzianum* has been shown to degrade plant pathogens, such as *Schlerotium rolfsii, Rhizoctonia solani,* and *Pythium aphanidermatum.* Plant nematodes, *Criconemella xenoplax,* have been suppressed by the fungus *Hirsutella rhossiliensis.* Here again, researchers are faced with a very complicated biological system in which a tremendous amount of basic research must be conducted before biological control of plant pathogens can be realized to its full potential.

5. Other Biological Methods of Control

5.1. Biochemicals

Interfering with an insect's growth to make the insect vulnerable to natural control measures and maintaining an insect in a "nonpest" developmental stage have long been intriguing ideas for insect control. During normal insect development, immature stages are regulated by hormones (growth regulators). During the adult stage, insect behavior is influenced by pheromones and kairomones (semiochemicals).

5.1.1. Growth Regulators

Ecdysone is secreted by the prothoracic glands and initiates cell growth. Once released into

the hemolymph, ecdysone causes the insect to molt. α-Ecdysone [*3604-87-3*], $C_{27}H_{44}O_6$, M_r 464, *mp* 237 – 239 °C, is a water-soluble crystalline compound; IR (KBr, cm^{-1}) 3333, 1657; UV (MeOH) 242 nm (ε 12400); NMR (C_5D_5N) [46]. It was originally isolated from silkworm

α-Ecdysone

pupae. β-Ecdysone [*5289-74-7*], 20-hydroxy-α-ecdysone, is a slightlymore biologically active compound. Both α- and β-ecdysone are biosynthesized from cholesterol [47]. Phytoecdysones, steroids with molting hormone activity, have been isolated from several plants. The isolation and synthesis of phytoecdysones and α- and β-ecdysone have been described in detail [47]. Exogenous ecdysones will initiate molting in insects when applied to the surface of the cuticle.

Juvenile hormones (JHs) are synthesized in and secreted by the corpus allatum. These hormones stimulate larval development while preventing development of adult characteristics. They also promote synthesis of yolk proteins and accumulation of these proteins by the developing oocytes. Juvenile hormones control the development of imaginal discs. Application of JH to a young embryo will block its development to a larva; however, JH may be important in normal embryonic development of some insects.

Five juvenile hormones, JH 0 [*55333-14-7*], iso-JH 0, JHsI [*13804-51-8*], JH II [*34218-61-6*], and JH III [*22963-93-5*], have been isolated from insects. The JH I, II, and III are liquids, JH 0 and iso-JH 0 are presumed to be liquids; JH I *bp* 130 – 145 °C; IR (cm^{-1}) 1715, 1640, 1230, 1150, 850, 1730, 1655, 1722, 1650.

Juvenile hormone I

Juvenile hormone II

Juvenile hormone III

Juvenile hormone 0

iso-Juvenile hormone 0

Juvabione [*17904-27-7*], a juvenoid (compound with JH activity), was isolated from the balsam fir tree [48]; MS 266.188 (M^+ $C_6H_{26}O_3$); UV 223 nm; IR (cm^{-1}) 1722 (α, β-unsaturated ester), 1645 (saturated ketone).

Juvabione

Several other juvenoids have been isolated from plants [49]. The determination of the structure of the naturally occurring JHs led to the synthesis of JH-analogs. Syntheses of JHs, juvenoids, and JH-analogs have been reviewed [50], [51]. Commonly used synthetic JH-analogs are: methoprene [*40596-69-8*], Altosid, ZR 515, *mp* 135 – 136 °C, d^{20} 0.926; hydroprene

[*41096-46-2*], Altozar, ZR 512; epofenonane [*57342-02-6*], RO 10-3108. The applied use and chemistry of these and other JH analogs have been thoroughly discussed [52].

Methoprene

Hydroprene

Epofenonane

Two compounds, precocene 1 [*17598-02-6*] and precocene 2 [*644-06-4*], isolated from the common bedding plant, *Ageratum houstonianum,* have anti-JH activity against several hemipteran species [53]. Precocenes destroy the corpora allata of insects in the orders Hemiptera, Homoptera, and Orthoptera. There is no anti-JH activity against holometabulous insects; however, certain ones have been forced into diapause, have been sterilized, or both. Synthesis of precocenes has been described [54].

Precocene 1, R = H
Precocene 2, R = OCH_3

Leaves of the neem tree, *Azadirachta indica,* yield chemicals that are strong antifeedants [55], [56]; however, these chemicals have not led to any significant use for pest control. The main component of the neem fractions is azadirachtin [*70357-01-6*], $C_{35}H_{44}O_{16}$, a compound that acts as a phagorepellent and as a growth regulator; UV(MeOH) 217 nm (ε 9100); CD (MeOH), no extrema above 220 nm; IR (KBr, cm^{-1}) 3410, (OH) 1745, 1720, 1700 (esters), 1645, 1620, 843 (double bonds); IR (chf. concentration variation) 3580 cm^{-1} (free OH), 3465 (intramolecular bonded OH), 3380 (intermolecular H bonded OH).

Azadirachtin

5.1.2. Semiochemicals

Pheromones. A pheromone is a substance that is secreted by an organism to the outside and mediates a response in an organism of the same species. Sex pheromones are specific chemicals used in the mating process. Generally, they are emitted by the female insect and attract the male insect. Chemical structures of pheromones are scattered among many types of volatile compounds ranging from alkanes to nitrogen heterocycles. Earlier research usually reported one chemical as the pheromone of an insect. Synthesis of these compounds and field testing for attractancy has resulted in various degrees of success. However, although a single compound is the major component, there are trace amounts of additional chemicals that make up the full complement of the pheromone [57–59].

Using open-tubular capillary chromatography analysis, the following composition was determined for the pheromone of the lesser cornstalk borer, *Elasmopalpus lignosellus*: 16.5 % (*Z*)-7-tetradecen-1-ol acetate, 8.8 % (*Z*)-9-tetradecen-1-ol acetate, 3.8 % 1-tetradecanol acetate (C_{14}), 28.2 % (*Z*)-9-hexadecen-1-ol acetate, 17.4 % (*Z*)-11-hexadecen-1-ol acetate, 9.6 % 1-hexadecanol acetate (C_{16}), 2.1 % (*Z*)-7-tetradecen-1-ol, 2.1 % (*Z*)-9-tetradecen-1-ol, 7.0 % (*Z*)-9-hexadecen-1-ol, and 4.4 % (*Z*)-11-hexadecen-1-ol [59]. The organic synthesis of sex pheromones has been reviewed [50], [60], [61]. Biosynthesis of pheromones takes place in a glandular area of the abdominal tip of the adult female and is regulated by a hormonal factor produced in the brain [62].

Several pheromones have been synthesized and these synthetic pheromones are available for certain pests of agricultural crops [63].

Kairomones. Kairomones are compounds given off by one species that induce a greater behavioral response in another species than in the species exuding the compound. Kairomones include host-seeking chemicals, e.g., compounds that aid parasitoids in search of suitable hosts. Host-seeking compounds, extracted from the wings (scales) of *Heliothis zea* and *Cadra cautella,* increase parasitization of eggs by *Trichogramma evanescens.* These compounds stimulate the parasitoid to search for suitable host eggs.

Some plants produce substances that attract insects, e.g., cucurbitacins. Cucurbitacins are oxygenated tetracyclic triterpenes produced by plants of the family Cucurbitaceae, i.e., Cucurbitacin B [*6199-67-3*]. A complete discussion of the chemistry of these compoundsis available [64].

Cucurbitacin B acetate

The fruits of wild species of *Cucurbita* contain amounts of these chemicals that are toxic to animals. Cucurbitacins are also present in extremely small quantities, < 0.02 mg/g, in domesticated fruits of *C. ficifolia, C. maxima, C. mixtra, C. moschata,* and *C. pepo* [65]. This small amount, however, acts as an arrestant (kairomone) and feeding stimulant to several beetles in the genus *Diabrotica* [66].

5.1.3. Bioderived Toxicants

Some organisms produce chemicals that are mere poisons without any novel mode of action, such as an attractant and/or growth regulator. The avermectins are a class of compounds described as pentacyclic lactones isolated from fermentation of the actinomycete *Streptomyces avermitilis.* These natural products contain an α-L-oleandrosyl-α-L-oleandrosyl disaccharide attached to the macrocyclic lactone ring through the allylic C_{13}-hydroxy group [67]. These compounds have demonstrated toxicity in laboratory and field tests against several insect pests, phytophagous mites, and a plant parasitic nematode.

Avermectin	R^1	R^2	R^3	CAS-Reg. No.
A_1a		C_2H_5	CH_3	[*65195-51-9*]
A_1b		CH_3	CH_3	[*65195-52-0*]
A_2a	OH	C_2H_5	CH_3	[*65195-53-1*]
A_2b	OH	CH_3	CH_3	[*65195-54-2*]
B_1a		C_2H_5	H	[*65195-55-3*]
B_1b		CH_3	H	[*65195-56-4*]
B_2a	OH	C_2H_5	H	[*65195-57-5*]
B_2b	OH	CH_3	H	[*65195-58-6*]

Where R^1 is absent, the double bond (=) is present. Both sugars are α-L-olendrose.

5.2. Autocidal

Autocidal methods involve alteration of genetic material of insects, thereby reducing the insect's ability to reproduce. Briefly, after the genetic material of an insect population is altered, this population is released into nature. Mating of the genetically abnormal population with the wild population causes reduction in the natural population.

5.2.1. Sterile Male

The primary autocidal method is the sterile male technique in which tremendous numbers of male insects are sterilized either by radiation or by chemical means, and released into natural populations in such numbers that the sterilized males greatly outnumber the naturally occurring ones. This technique has been employed with success against the screwworm, *Cochliomyia hominivorax,* Mediterranean fruit fly, *Ceratitis capitata,* melon fly, *Dacus cucurbitae,* Mexican fruit fly, *Anastrepha ludens,* and pink bollworm, *Pectinophora gossypiella.*

5.2.2. Hybrid Sterility

Hybrid sterility involves the crossing of two closely related but different species of insects with production of sterile progeny and subsequent release in natural populations. These hybrids must be fully viable and able to compete with feral adults. Other genetic alterations are: (1) cytoplasmic incompatibility – certain strains within a species when crossed produce either sterile offspring, or sterile and fertile offspring, or sterile males; (2) conditional lethals – certain alleles of genes controlling adaptability produce normal effects at certain temperature ranges but produce lethal effects at higher or lower temperatures; (3) growth alterations – for example, introducing a gene for "nondiapause" into a strain of insects that must diapause in order to survive the winter.

6. Formulation, Application, and Efficacy

Insect Control. Formulation and application of biological control agents are a "hand-in-glove" type of relationship. The proposed use of an agent dictates to a great extent the way in which that agent must be formulated to elicit its greatest possible impact. Formulation must be done with the recognition that biological control agents are living organisms which vary in their susceptibilities to adverse environmental conditions.

The formulation techniques for parasitoids and predators are limited. Basically, these insects are colonized, produced in large numbers in an insectary, and then released into the environment at a time predetermined to be most advantagous to the beneficial insect.

A special case of formulation and application of parasitoids is employed when *Trichogramma* are used in applied biological control. Briefly, *Sitotroga cereallella* or *Anagasta kuehniella* adults are constrained to lay many eggs on sheets of cardboard; these eggs are parasitized by *Trichogramma* adults, and the cards of parasitized eggs are placed in an ecosystem containing recently oviposited eggs of a pest insect. This procedure is timed so that the *Trichogramma* will emerge within a few hours after being placed in the environment. *Trichogramma maidis* is utilized in eastern France to control populations of the European corn borer in corn. Researchers obtained 90 – 95 % control by placing 300000 parasitized *Anagasta kuehniella* eggs/ha [68] in corn fields infested with the European corn borer. Techniques also have been developed to apply *Trichogramma* with a crop-dusting plane. The host eggs are sometimes oviposited on a carrier, such as wheat bran, and this admixture is air – dropped over an insect-infested crop area.

Pediobius foveolatus, a parasitoid of the Mexican bean beetle, was released annually in Maryland. Approximately 490000 parasitoids were released over 94000 ha of soybeans, resulting in up to 84 % parasitism of the Mexican bean beetle [69].

Excellent control of aphids on potatoes was obtained by releasing a lacewing, *Chrysopa* spp., and a coccinellid, *Coccinella septempunctata,* at the same time. These researchers released 210300 and 74600/ha of *Chrysopa* and *C. septempunctata,* respectively [70].

Pathogens are formulated in the same way that chemical insecticides are, i.e., as dusts, wettable powders, flowable concentrates, granules, or baits. An insect-pathogen dust or granule is made by mixing the pathogen with an inert material called a diluent. Diluents most often used are talcs, prophyllite clays, clays, calcium carbonate, precipitated hydrated silicates, silicon dioxides, synthetic calcium silicate, and diatomaceous earth. Potato starch, cornstarch, wheat flour, wheat bran, ground corn cobs, and ground corn have been used as experimental diluents. The basic differences between a dust and a granule is the mere size of the diluent.

Wettable powders are formulations of pathogens containing sufficient wetting agent that the pathogen will be wetted and suspendible in water. Powders can be any of the named diluents, only finely ground, so that a sprayable end product is obtained. A flowable concentrate is essentially a wettable powder suspended in an oil or liquid base of some type that can readily be mixed with water to form a stable suspension.

Baits usually are botanical products, such as apple pomace, grape pomace, citrus pulp, wheat bran, etc., that are food sources and attract the target insect.

In all these formulations, great care is taken to assure shelf life, stability in the field, and mainte-

nance of viability of the pathogen. Commercial additives are available to protect the pathogen from severe drying or wetting and from ultraviolet light.

Wettable powder and flowable concentrate formulations are employed when complete coverage of an area or vegetation is necessary for maximum efficiency. The use of *Bacillus thuringiensis* subspecies *israelensis* for mosquito and black fly control is a situation in which these formulations are used.

Two wettable powder formulations of *B. thuringiensis* subspecies *israelensis,* Bactimos (Biochem Products, USA) and Vetobac (Abbott Laboratories, USA), and a flowable concentrate, Teknar (Sandoz, USA), were tested against mosquito populations in central Italy [71]. Bactimos and Teknar were applied at 0.5 kg/ha and 2.5 L/ha, respectively, to control the mosquito *Aedes caspius* in a salt marsh. These applications gave complete control of the larvae. Vectobac at 0.5 kg/ha gave a range of 67 – 91 % control. A flowable concentrate formulation of Teknar was prepared to give a concentration of 10 ppm and applied to the width of a fresh water stream for 1 min with complete elimination of the black fly larvae [72].

Aqueous suspensions of insect viruses are prepared from wettable powder formulations. Viruses are quantified as polyhedral inclusion bodies (PIB) per unit mass. The European pine sawfly, *Neodiprion sertifer,* can be controlled on *Pinus resinosa* with an application of 2.5×10^9 PIB/ha [73]. Application rates of this magnitude have been used to control other forest pests [74] and pests of other agricultural crops, i.e., cole crops, cotton, and soybeans [75]. Granular formulations are used in an ecosystem for placement of a pathogen on a plant or within a certain area, or for incorporation into soil. For example, larvae of the European corn borer feed on a corn plant at the interface where the developing leaves are unfolding. Because of the morphology of the plant, there is a natural funnel that will direct granules of a pathogen to this area and thus make them immediately available for consumption by the insect. Not only is the pathogen more readily available to the insect, but also it is protected from ultraviolet radiation.

An 11.25 wt % formulation of Thuricide HPC on clay granules was applied at 1.12 kg of *B. thuringiensis* HPC/ha to control the European corn borer on corn [76]. This application caused a significant reduction in damage by the borer compared to the untreated check. Several mosquito habitats are in areas of heavy vegetation. A granular formulation, when applied in this type of environment, will pass through the vegetation, enter the water, and become available to the mosquito larvae. Granular formulations of *Bacillus popilliae* are incorporated into soil for control of Japanese beetles in Russia [77]. A specialized formulation and application is the impregnation of foundation wax with *Bacillus thuringiensis* subspecies *galleriae* for control of greater wax moth larvae in beehives [78]. *Nosema locustae* is formulated as a bait on wheat bran and applied to rangeland to control grasshoppers at 2.5×10^9 *N. locustae* spores on 2 kg of wheat bran/ha [79]. This application reduced the population of immature grasshoppers by 50 %. A similar treatment effectively reduced populations of the Mormon cricket, *Anabrus simplex* [80]. Nematodes, *Neoaplectana carpocapsae,* applied as an aqueous suspension ($\geqq$ 1000 nematodes/mL) were highly effective against larvae of the artichoke plum moth, *Platytilia cardiudactyla* [81]. The neoaplectanid nematodes show potential for control of several insect pests [82]. *Romanomermis culicivorax,* a nematode parasite of mosquitoes, has been tested worldwide for mosquito control. Different stages of the nematode, egg, pre-, and postparasitic, are applied to the aqueous environment at rates of a few hundred to 200000 units/m^2 with varying degrees of success. A wettable powder or dust formulation of *Hirsutella thompsoni,* a myoacaricide, was effective in stimulating premature fungal epizootics in citrus rust mite populations [83].

The environs of a greenhouse create special pest problems but also present a controllable situation for the use of biological control agents. The successes, problems, and failures of biological control in such ecosystems have been reviewed [84], [85]. In a greenhouse-like situation, the spotted spider mite, *Tetranychus urticae,* was controlled in a plastic walk-in tunnel by introducing one predatory mite per strawberry plant [86]. Control of the greenhouse whitefly, *Trialeuroes vaporariorum*, is difficult. A combination of attracting the whitefly to yellow sticky traps and using the parasitoid *Encarsia formosa* has resulted in 90 % parasitization of this pest on

spring tomatoes in the greenhouse [87]. In other research [88], several species of parasitoids with the potential of controlling the chrysanthemum leaf miner have been identified.

The use of fishes to control insects is primarily focused on controlling the larvae of mosquitoes that transmit human disease. *Gambusia affinis,* a larvivorous fish, is a native of the southeastern United States but has spread to most parts of the world where it can survive and give excellent mosquito control. *Gambusia affinis* seeded at 2500 – 5000 fish/ha will reproduce quickly and provide complete mosquito control in 6 – 8 weeks [89], [90].

Spiders definitely have an impact on control of insects; however, quantification is difficult [91].

Weed and Plant Pathogen Control. Mycoherbicides are also formulated as an aqueous suspension and sprayed on foliage for control of weeds. Spores of *Colletotrichum coccodes,* a fungus, were sprayed on velvetleaf, *Abutilon theophrasti,* at 10^7 and 10^9 spores/m^2 in 467.5, 935, and 1870 L of H_2O/ha. These concentrations of spores reduced the velvetleaf biomass by 40 and 50 % at the 10^7 and 10^9 treatment levels, respectively [92]. Progress has been made using a rust, *Puccinia chondrilla,* to suppress rush skeletonweed, *Chondrilla juncea* [93]. Plant size, number of flowers, and seed viability have been reduced, but there has been no substantial reduction in plant populations.

Damage caused by the root-knot nematode *Meliodogyne javanica* has been reduced using biological control. Tomato roots containing the nematode infected with *Bacillus penetrans* were air-dried, finely ground, and incorporated into the soil at 212 – 600 mg/kg, reducing the number of nematodes and the damage caused by the nematodes [94]. Organic extracts from the fungus *Aphanocladium album* induce teliospore formation on rust fungi. *Puccinia graminis, P. dispersa, P. striiformis,* and *P. sorghi* formed premature telia on plants treated with the extract [95]. The biology of introduced predators and parasitoids of arthropod and weed pests is available [96].

Other Methods of Biological Control. Growth regulators have been tested for insect suppression. Lethal effects were induced in a population of western spruce budworms at dosages comparable to several conventional insecticides [97]. Treating male or female adults of the western spruce budworm with ZR575, ZR512, or RO 10-3108 reduced the reproductive potential of these insects [98]. Precocene 1 and 2 deterred *Heliothis zea* larvae from feeding in laboratory studies, resulting in starvation [99].

Azadirachtin from the neem tree interfered with molting of the face fly, *Musca autumnalis,* when larvae were exposed to concentrations as low as 0.00001 µg/mL [100]. The application of 2 µg of azadirachtin/larva killed 92 – 100 % of Japanese beetle, *Popillia japonica* [101].

Insect pheromones have potential for several uses in insect management, e.g., monitoring populations, trapping insects to a point source, and interfering with mating. The science of insect pheromones involves several steps, from isolation, identification, and synthesis of the pheromone to learning the behavioral change that these chemicals manifest in a target insect. The state of the art of pheromones has been reviewed [102]. Minute amounts of the pheromone of a given species of insect will attract the male. In some insects, several compounds constitute the pheromone. In *H. zea,* maximum male response is elicited with compounds (*Z*)-7-hexadecenal, (*Z*)-9-hexadecenal, (*Z*)-11-hexadecenal, and hexadecanal, whereas *H. virescens* males respond to a mixture of the above chemicals plus (*Z*)-9-tetradecenal, tetradecanal, and (*Z*)- 11-hexadecen-1-ol [57], [58]. The female sex pheromone of the lesser cornstalk borer, *Elasmopalpus lignosellus,* is composed of 10 compounds (Section 5.1.2). A mixture of four of these compounds, 91.6 µg of (*Z*)-11-hexadecen-1-ol acetate, 11.2 µg of (*Z*)-9-tetradecen-1-ol, 46.4 µg of (*Z*)-9-tetradecen-1-ol acetate, and 86.8 µg of (*Z*)-7-tetradecen-1-ol acetate applied to a rubber septum produced maximal capture of lesser cornstalk borer females [59].

Cucurbitacins act as kairomones to beetles in the subtribe Diabroticites, which includes several species that feed on Cucurbitaceae. This tribe also includes the corn rootworm beetles. Amounts as small as 0.003 µg cause complete arrest of these beetles. If they pass by a point source, they stop and begin compulsive feeding until the food source is depleted [66]. Re-

searchers have demonstrated a strong correlation between total Cucurbitacin content and the extent of aggregation and feeding by two species of *Diabrotica.* Other researchers have proposed using fruits of Cucurbitaceae coated with a chemical insecticide to bait insects to a point source and kill them [103].

Bioderived Toxicants. Ivermectin [*70288-86-7*], 22,23-dihydro derivative of avermectin, is active at extremelylow dosages against a wide variety of arthropod parasites and nematodes [104]; i.e., 0.001 mg/kg is effective against immature stages of *Dirofilaria immitis,* when administered orally to dogs. Also, 0.02 mg/kg is efficacious against *Haematopenus suis* when injected subcutaneously in hogs. A subcutaneous dosage of 200 µg/kg killed blood sucking flies on steers [105]. Pheromone production was significantly reduced when adult boll weevils, *Anthonomus grandis* were topically treated with 7 µg of avermectin B_1 [106].

The sterile autocidal male technique has been used successfully but depends on the ability to rear large numbers of insects for sterilization and release. The screwworm, *Cochliomyia hominivorax,* has been eliminated from Curaçao and southeastern United States. A program is ongoing to suppress the screwworm in Mexico and inhibit its spread to the southwestern United States. To accomplish this, ca. 350×10^6 sterile flies are released weekly. The established population of flies has been pushed back in excess of 600 km from the United States – Mexican border.

The sterile insect technique is a major component of the Mediterranean fruit fly, *Ceratitis capitata,* program in California. Up to 40×10^6 flies are released weekly, enabling success in keeping this pest out of California.

An extensive program has been undertaken to suppress populations of the codling moth, *Laspeyresia pomonella,* in the state of Washington, United States, and British Columbia, Canada. The codling moth is widely distributed and feral populations continually migrate into suppression areas rending the program ineffective.

Other autocidal techniques are generally on an experimental basis. The hybrid sterility technique crossing *Heliothis virescens* males with *H. subflexa* females has been tried experimentally in Puerto Rico, indicating a good potential for infusion of the sterility factor into the native population [107].

Whenever a component is used to manage a pest population, the question of **safety** arises. Usually, pest control is undertaken to protect a commodity that is in the food chain which eventually is consumed by humans. Thus, human safety is extremely important. Recently, safety to the environment and to the ecological balance has become recognized as important. The organisms and chemicals discussed in this article are entities that are indigenous to a certain ecological niche or they are synthesized chemical compounds that are an instrumental part of nature. Thus, if these components are used within the environmental framework from which they evolved, safety is relatively assured.

Exhaustive lists are available for some organisms, stating which target and nontarget organisms are susceptible [108]. For others, guidelines for safety tests and registration have been established [109], [110]. In depth studies have been conducted examining the effect of insect nuclear polyhedrosis viruses in mammalian cells [111], with no consistent deleterious effects directly attributable to the viruses being observed.

Prior to inoculative releases, phytophagous insects and plant pathogens that are candidate biological control agents are subject to exhaustive host range studies to be certain that the introduced species will not become pests in a different ecosystem.

In general, the biological control agents discussed here will not have a detrimental impact when used sensibly in an integrated pest management program.

1. Introduction

Biomass chemicals are those chemicals made from renewable, organic materials. Most biomass materials are plant products or wastes, but animal products, such as fats or manures, also are included.

Although this category enjoyed renewed interest because of the oil crises during the 1970s, biomass chemicals are not new inventions. In fact, at one time, the chemical industry was largely based on chemical products made from wood, sugars, starches, and animal fats (→ Wood, → Sugar, → Starch, → Polysaccharides, → Fats and Fatty Oils) [1].

Some biomass chemicals are still staples of chemical industry. Cellulose fibers, for example, command large markets even after years of competition from petroleum-based materials. Many other biomass chemical processes were in operation until the 1960s, and some are still operating in developing nations or in countries without ready access to petroleum [2]. Among the biomass chemicals that are, or were, important are ethanol, acetone/butanol, itaconic acid, lactic acid, xanthan gum, sorbitol, industrial starches, fatty acids and alcohols from vegetable and animal sources, glycerol, soap, furfural and its derivatives, rayon, cellophane, carboxymethylcellulose, lignosulfonates, tall oil, vanillin, and methanol.

During the oil shocks of the 1970s, a number of chemical companies decided to take another look at biomass chemicals [3]. In the United States, the biomass chemical receiving the most attention was ethanol made by fermentation of grain (→ Ethanol). Ethanol was, at that time, vigorously supported by the federal government as a gasoline extender and octane enhancer. Other biomass-based commodity chemicals receiving attention at that time were methanol, acetic acid, butanol/acetone, and ethanol derivatives.

Petroleum prices have stabilized and most United States' chemicals producers have abandoned their interests in biomass commodity chemicals [3]. However, several manufacturers are developing new lines of biomass specialty chemicals, such as novel starch polymers [1], [2, p. 147], [4], new lignin chemicals [4–6], and polysaccharide gums [3].

The rapid rise and fall of interest in biomass chemicals parallels, in part, the curve of petroleum prices, but other characteristics of biomass chemicals have contributed to the cautious attitude toward their redevelopment. These characteristics and the potential for development and manufacture of new and old biomass chemicals are detailed in the following sections.

2. Raw Materials

One major problem in organizing production of biomass chemicals is the diversity of materials from which these chemicals may be made. The biomass *feedstock* category is vast; it includes grains, sugar crops, oilseed crops, agri-

10.1002/14356007.a04_099

cultural wastes, food processing wastes (liquid and solid), wood, wood chips, bark, mill residues, forest residues, pulping liquors, animal fats, manures, algae, and exotic crops, such as guayule, jojoba, and euphorbia.

All biomass materials contain carbon, hydrogen, and oxygen, but the chemical *composition* of each type of material is unique. Because most biomass materials contain considerable amounts of oxygen (as much as 40 %), they are generally considered to be most useful as sources of oxygenated chemicals [7], [8].

The diversity of biomass materials means that each biomass chemical *process* must be designed to use a specific type of material. Unlike petroleum, which is a much simpler, more homogeneous material, biomass from different sources is not interchangeable.

Production and *collection* of biomass feedstocks also present problems. If a process uses a well-known biomass feedstock, for example, starch, then production and collection is simple because a starch-processing industry already exists. However, use of starch for production of new chemicals or for increased production of conventional starch-based chemicals may create competition with existing starch markets. The same line of reasoning applies to the use of timber or pulp-grade wood as a feedstock for chemicals production.

If a nonconventional biomass feedstock is selected, agricultural residues, for example, then collection of this dispersed material poses logistical problems. In general, biomass wastes are bulky, dispersed, and difficult to collect and transport economically for any appreciable distance.

The biomass chemicals processes in operation today use conventional biomass feedstocks (sugar, starch, wood) or biomass wastes (forest residues, pulping liquors, agricultural residues). Investigations are under way on new crops, such as guayule, jojoba, euphorbia, or crambe, that can be grown on currently uncultivated land and used exclusively for chemicals production [9]. Some of these projects, as well as creation of short-rotation forestry projects, still need further development of production and collection infrastructures, processing industries, and markets.

3. Process Technology

Because biomass materials are complex in composition, *conversion* of these substances to chemicals is often inefficient [1], [10]. Plant materials, for example, contain three major components: cellulose, hemicellulose, and lignin (→ Cellulose, → Lignin). If a chemical process uses only one component and the others become wastes that must be disposed, the process often becomes uneconomic. In traditional wood pulping, for example, cellulose for cellulose fiber and chemical production is separated from lignin and hemicellulose fractions, which are usually burned for their energy content or occasionally made into specialty chemicals. New wood chemicals processes would almost certainly have to include higher-value uses for the lignin and hemicellulose. Some biomass experts have suggested that a "biomass refinery" concept is necessary to any successful biomass chemicals plan in the future [4], [11].

Separation of the components of lignocellulose materials without intensive use of chemicals and energy, as is done in traditional wood pulping, is no easy matter. Development of new process technology that would convert the six-carbon sugars of wood cellulose to ethanol has been slowed considerably by the separation problem, although it was the subject of intensive research [10].

Biomass chemicals made from a purified component of lignocellulose are often produced via *fermentation.* Feedstock for these chemicals, which include ethanol, butanol/acetone, citric acid, and xanthan gum, is usually sugar or starch [2, pp. 5, 71]. Fermentation is a well-established process, but there are some problems in its wider application to chemical production. A typical fermentation produces a dilute product stream containing 10 % or less of the desired product, which must then be concentrated. Ethanol is usually separated from the fermentation beer by energy-intensive distillation. There has been much research and development on ethanol separation and progress has been made, but the problem is by no means eliminated [8].

Biomass chemicals may also be made by *chemical conversion* routes. Chemically modified industrial starches are produced by this route, as are the starch-based polymers [1], [2, pp. 137 – 154]. Vegetable-oil-based fatty acids

and alcohols are other products manufactured via chemical process routes [2, pp. 155 – 223].

Because separation of biomass components is often difficult and costly, some biomass chemicals are made by *thermochemical routes* that use the entire material. The destructive distillation of wood to methanol [*67-56-1*] is the oldest and best known example of this type of process(→ Methanol). The newer processes gasify biomass to synthesis gas, then reform it to methanol (→ Gas Production).

Biomass may also be *gasified* to methane or pyrolyzed to tars and liquid hydrocarbon products. Most work on gasification and pyrolysis for chemical production is in the laboratory or in early pilot plant development [12].

Another whole material chemical conversion route involves *anaerobic digestion* of biomass solids or liquids. Developed as a method for treating liquid sewage, methane-producing anaerobic digestion was initially conceived as a less energy-intensive method of reducing chemical oxygen demand of wastes. The process was also explored as a means of producing pipeline-quality methane.

4. Biomass Chemicals

4.1. Ethanol and Its Derivatives

The biomass chemical that has attracted the most interest in the early 1980s was ethanol [*64-17-5*] (→ Ethanol) [1], [4], [13]. In the United States, production of fermentation ethanol for use as a fuel extender was supported by a fuel tax exemption that extended to the end of the 1980s. The effect of this tax incentive has been a large growth in production of fuel and industrial-grade fermentation ethanol. Industrial grade fermentation ethanol is displacing synthetic ethanol in the chemicals market and some analysts predicted that the industrial ethanol market would be dominated by fermentation ethanol by 1990 [13].

Fuel ethanol is made by traditional batch fermentation of starches or sugars with the yeast *Saccharomyces cerevisiae.* New continuous fermentation processes are approaching commercialization [14].

Biomass-based ethanol may be converted to other large-volume commodity chemicals. Ethanol may be converted to ethylene by passing ethanol vapor over a heated fixed-bed alumina catalyst. The ethylene – water mixture is quenched and the two components separated [2, pp. 40 –47]. Although this route would be prohibitively expensive in countries with a well-developed petrochemical industry [1], [7], the ethanol-to-ethylene method is used in Brazil, which has a large government-supported fermentation ethanol program.

Acetaldehyde, now made via a petrochemical route, can also be produced from ethanol (→ Acetaldehyde, Chap. 4.1.). Ethanol is vaporized and passed over a heated, fixed-bed chromium-activated copper catalyst. Hydrogen is separated from the acetaldehyde and untreated ethanol is recycled. Acetaldehyde may also be converted to *n*-butanol via acetaldol and crotonaldehyde, although this process is expensive [2, pp. 48 – 54].

Butadiene was once produced from ethanol in a single-step process in which acetaldehyde and ethanol were passed over a tantalum oxide on silica gel catalyst. Energy intensive distillation operations necessary for product purification make this process expensive [2, pp. 62 – 70].

4.2. Other Fermentation Chemicals

Although ethanol production is the best known chemical fermentation process, there are many others. The butanol/acetone fermentation, still operated in South Africa, was once of great industrial importance (→ Acetone, Chap. 4.6.; → Butanols). Raw material for the process is grain or molasses, and the anaerobic fermentation uses the bacterium *Clostridium acetobutylicum.* The fermentation process produces a 60 : 30 : 10 mixture of butanol/acetone/ethanol, which must be separated by distillation [2, pp. 76 – 83].

Submerged aerobic fermentations for antibiotic production, initially developed during World War II, opened up new chemical production routes. Citric, gluconic, and itaconic acids are made by this route, as is xanthan gum, a polysaccharide with applications as a thickener, emulsifier, and stabilizer of food products (→ Citric Acid, → Gluconic Acid, → Polysaccharides) [15]. Xanthan gum and other similar polysaccharides may have poten-

tial as oil recovery agents or in oil clean-up applications [16].

4.3. Sugar Chemicals

Pure dextrose, usually obtained from starch, is the raw material for manufacture of sorbitol, a well-established chemical used in foods, dentifrices, and cosmetics, and as a chemical intermediate (→ Sugar Alcohols) [2, pp. 129 – 136]. Sucrose polyols also have a role in urethane foam manufacture.

4.4. Starch Chemicals

More than half the starch isolated from grains and potato crops is converted into sugars. The remainder has many industrial applications (→ Starch). Industrial starch may be used as is or it may be modified by partial depolymerization to dextrins or by chemical reactions that replace the hydroxyl groups of the dextrose unit with other substituents. Among the many modified starches are oxidized starch, acetates, phosphates, amino alkyl ethers, and other ethers. These large-volume, inexpensive materials are used as paper and textile sizes and as binders [2, pp. 137 – 146].

Some more drastically modified starch chemicals have also been introduced. A starch-acrylonitrile graft copolymer, developed and licensed by the USDA, has specialty uses in personal care products and in medical applications. A starch slurry is treated with acrylonitrile in the presence of a ceric ammonium nitrate catalyst in nitric acid. The product, called "Super Slurper," absorbs hundreds of times its mass in water [2, pp. 147 – 154].

Another starch-based chemical is α –methyl glucoside, a starch polyol used in production of rigid urethane foam (→ Polyurethanes) [7].

4.5. Oilseed Chemicals

Linseed, soybean, cottonseed, coconut, palm, and other plant oils and animal fats have always been important raw materials for chemical manufacture. These oils contain a mixture of triglycerides of fatty acids in the 8 to 20 carbon range.

Although biomass fatty acids have suffered from competition from petrochemical equivalents, they still retain sizable market shares in surfactants, paint binders, and plasticizers.

Natural fatty acids are made by hydrolyzing fats or plant oils with high-pressure steam, which requires investment in high-pressure equipment plus extensive vacuum distillation capacity to fractionate the acid mixture. The products find big markets, however, in surfactants, plasticizers, greases, synthetic lubricants, cosmetics, toiletries, textile chemicals, emulsifiers, secondary petroleum recovery products, and mineral beneficiation [2, pp. 155 – 223]. Processes and markets are described in more detail under → Fatty Acids.

Triglycerides also yield long-chain fatty alcohols, which have lubricant and surfactant applications. Soap, another natural oil product, has lost ground to synthetic detergents, but glycerol, which is a byproduct of soap or fatty acid manufacture, holds its own against synthetic glycerol.

Fatty acid derivatives, such as azelaic and pelargonic acids, formed by ozonolysis from oleic acid, find niches in specialty markets. Azelaic and pelargonic acids are used in modified polyester fibers, elastomers, adhesives, plasticizers, synthetic lubricants, and surface coatings. Nylon 11, made from ricinoleic acid derived from castor oil, is marketed as a plastic for molded parts in automobiles, conveying equipment, and other machinery. Other specialized nylons may also be made from natural fatty acids. Nylon 9 is derived from soybean oil; nylon 1313 is made from erucic acid from crambe oil.

Jojoba oil, extracted from the seed of the jojoba plant, an exotic desert shrub, is used in cosmetics. Its structure is very close to that of sperm oil, now on the proscribed list in many nations because of efforts to save the near extinct sperm whale. Jojoba oil producers are trying to introduce the oil, an ester of a long-chain fatty acid and a long-chain alcohol, into the high-pressure lubricant market and perhaps to the automobile lubricant market [9].

4.6. Furfural and Its Derivatives

Furfural (2-furaldehyde) [*98-01-1*] and its-derivatives, furfuryl alcohol [*98-00-0*], furan

resins, and tetrahydrofuran [*109-99-9*], are produced in many countries from corn cobs, wheat and oat hulls, and many other biomass materials (→ Furan and Derivatives, → Tetrahydrofuran). *Furfural,* which is derived from the pentoses (five-carbon sugars) present in hemicellulose, one of the major components of lignocellulosic materials, is produced by steam treatment followed by dehydration. Furfural was often mentioned in the early 1980s as a possible new product for developing countries with plentiful biomass resources, and several nations have successfully established plants [13].

One-third of the furfural produced is used as a solvent; the other two-thirds is used as an intermediate in the manufacture of furfural derivatives. The most important *furfuryl alcohol,* used to produce furan resins for foundry sand binders. Another derivative, *tetrahydrofuran,* can also be produced via a petrochemical route. Other uses for furfural, such as production of adiponitrile, might be found if furfural prices were reduced by expanded production [13].

4.7. Cellulose Polymers

Cellulose polymers, such as rayon, cellulose acetate, cellulose ester, cellophane, and modified cellulose, are still important in spite of heavy competition from petrochemical alternatives. Markets and process technology for these chemicals are described more fully under → Cellulose, → Cellulose Esters.

Interest in cellulose stems from alternative fuel research growing out of the oil crises of the 1970s. Cellulose is viewed as a possible source of hexose sugars, which can be fermented to ethanol. New lignocellulose fractionation schemes resulting from the cellulose-to-ethanol research may contribute novel pulping technologies that will preserve the value of the hemicellulose and lignin fractions of the lignocellulosic materials [4], [10].

4.8. Lignin Chemicals

Paper pulp mills have long produced vast waste streams containing the lignin (→ Lignin) and hemicellulose fractions of wood. These waste streams, which contain chemicals from the pulping process, are usually burned for their energy value, but a small portion is converted to a variety of chemicals.

Neutral sulfite semichemical pulping yields a black liquor from which acetic and formic acids may be extracted. Kraft black pulping liquor may be a source of dimethyl sulfoxide, which is made by heating the liquor to convert the lignin methyl groups to methyl sulfide. Oxidation then produces dimethyl sulfide [2, pp. 295 – 302].

Sulfonated lignins, a major component of Kraft black liquor, can be recovered as lignosulfonates, which are used as dispersants, sequestrants, emulsion stabilizers, and humectants. Crude calcium lignosulfonate can be oxidized to vanillin, which competes with the extract from the vanilla bean [2, pp. 311 – 319].

Tall oil is a byproduct of the Kraft process for pulping softwoods. Tall oil is a mixture of rosin and a group of fatty acids (→ Tall Oil) [2, pp. 320 – 328].

New lignocellulose separation processes, such as steam explosion, have led to production of an unmodified, low-molecular-mass lignin [5]. Although this material has yet to be widely tested, it may be useful as a partial substitute for phenolic resoles in phenol – formaldehyde adhesives. Other uses for this type of lignin have also been suggested: binder for animal feeds, encapsulating agent, feed grain coating, road dust treatment chemicals, reinforcing fillers in rubbers, and setting agent in Portland cement [5]. In addition use of lignin copolymers in drilling muds has been discussed [17].

Some proponents of "biomass refining" suggest that lignin be hydrocracked and hydroalkylated to phenol and benzene [6], [11].

4.9. Methanol

The old route to biomass methanol, often called wood alcohol, was destructive distillation. In this method, 1 t of wood heated in steel ovens produces 0.25 t charcoal, 30 kg acetic acid, 10 kg methanol, and 60 L tar and oil from low-energy gas. This process is not economically feasible in industrialized countries although it might be in less developed nations [2, pp. 339 –347].

New methods of methanol production require gasification of biomass, often in an oxygen-

blown gasifier, to produce synthesis gas, which is then reformed to give methanol. Several projects are now in the pilot plant or demonstration stage (→ Methanol) [18].

4.10. Methane

There are several ways to produce methane [*74-82-8*] from biomass. The most widely used is anaerobic digestion, a conversion process originally developed for clean up of low-strength organic liquid wastes. Anaerobic digestion is a slow fermentation process in which a variety of bacteria convert organic matter first to organic acids and then to methane. Much experimentation is now going on in this field, with most applications being found in waste treatment [19]. Methane production in these applications is secondary, with gas produced being used to fuel the process. However, the process can be used for its methane-producing capacity alone. New reactor designs and process research make this possibility more likely (→ Methane).

5. Future Contributions

Biomass-based chemicals always have been important to the chemical industry and they are likely to remain so in the future. If their contribution is to grow, however, several conditions must be met.

First, *new markets* for biomass-based products must be identified. Although some have proposed constructing a chemicals industry based on four fermentation products [20], most authorities believe biomass chemicals must be introduced to specific target markets where they may replace petrochemical equivalents by indirect substitution [1], [4], [8]. Specialty chemicals from biomass are probably more likely to meet with success than commodity chemicals.

Second, *economic conditions* must be realistically assessed. Although production of many oxygenated chemicals could be based on starch, for example [7], [8], this is not likely to happen as long as petroleum and natural gas prices are stable. However, if these prices rise significantly, such commodity chemicals options might become more promising. Some government support of research and development is likely to be necessary in development of new commodity chemicals process technology [3].

Third, production of new biomass chemicals will likely involve *new collaborations* between producers of raw materials and chemical manufacturers. Such collaboration is now beginning between starch processing companies and a few chemical manufacturers. Forest products companies, which are likely suppliers of wood and wood wastes for chemical production, are much less interested at present in such collaboration [21].

Biotechnology can be regarded as one of the key technologies of the 21st century. It is the commercial application of living organisms such as bacteria, fungi, yeasts, plant cells, viruses, and mammalian cells or their products, which involves the deliberate manipulation of their DNA molecules. This article gives an introduction into the basics in microbiology and provides an exhaustive description of the relevant microbial species and metabolic pathways. Identification, analysis, and manipulation of the genome, proteome, and metabolome is described, and cultivation requirements as well as process parameters discussed. Biotransformation and enzyme technology plays a central role in industrial biotechnology, and a focus is given on the development of molecular engineering techniques and new screening methods. Computational Biochemistry comprises the definition, monitoring, and modeling of bioprocesses. Examples of biotechnology applications include mammalian cell technology, tissue engineering, and the production of relevant food additives as well as of various medical and pharmaceutical products. In conclusion, biotechnology offers manifold possibilities in industrial and medical applications.

1. Introduction

Biotechnology can be described as "the commercial application of living organisms or their products, which involves the deliberate manipulation of their DNA molecules". This includes the use of bacteria, fungi, yeasts, plant cells, viruses, and mammalian cells. This definition implies a set of laboratory techniques developed within the last 20 years that have been responsible for the tremendous scientific and commercial interest in biotechnology, the founding of many new companies, and the redirection of research efforts and financial resources

among established companies and universities. Thus, biotechnology can be regarded as one of the key technologies of the 21st century. However, the use of microorganisms and their products is as old as mankind. Fermented products with yeast such as beer, wine, or sake are known since several thousands of years (Table 1). The roots of modern biotechnology are coming from the era of microbiology, which was developed in the late 19th century. Cagniard-Latour, Pasteur, Koch and Kühne were important scientists who are decoding the principles of fermentation. The use of microorganisms for the production of bulk chemicals such as butanol or acetone and for pharmaceuticals (antibiotics) was strongly developed during World War I and II. With the better understanding of the gene function and its relation to the metabolisms of cells, the modern era of biotechnology started in the 70th of the last century.

Nowadays, biotechnology is a cross-sectoral technology that has been successfully applied in many industrial branches. One distinguishes between several areas or "colors" of biotechnology (the so-called red, white, green, and blue biotechnology).

Red Biotechology. Named as red biotechnology are applications in medicine or in the pharmaceutical industry. Red biotechnology has already made an impact on healthcare and will continue to contribute to improving human health and life expectancy. Today, 20 % of marketed medicines, 50 % of those in clinical trials, and 80 % in early development are biotech-based products. Forty percent of these candidate medicines are for the treatment of cancer. Typical products of red biotechnology are recombinant vaccines, antibodies, blood clotting agents, and hormones. In addition, tissue engineering is a part of the area of biotechnology. Tissue engineering aims at the functional regeneration of tissues through implantation of tissue cultured in vitro (see Section 9.2).

White Biotechology. The potential and applications of biotechnology in other sectors largely pass unnoticed especially in the chemical industry. The chemical industry has produced coal, gas, and petroleum-based goods and products for over 150 years. This era is likely to end within the next 100 years at the latest. An extrapolation of oil consumption from 2002 (3.3 billion tonnes), for example, yields a supply period of 50 years with estimated stocks of 165 billion tonnes. The underlying reasons for a future era of new raw materials are the finite nature of fossil resources on the one hand, and the connection with many environmental problems on the other hand. In the past few years conditions for the application of biotechnological processes in industrial production have improved

Table 1. Timetable of biotechnology [1, 2]

Year	Biotechnological progress
3000 b.c.	Fermentation of sugar containing juices to various alcoholic beverages
2800 b.c.	brewing rooms in Mesopotamia and leaven in Egypt
1500 b.c.	Use of microorganisms for the production of copper and production of soya sauce
300 b.c.	Use of vinegar
1300	Micro algae (*Spirulina*) as food additives (Aztecs)
1400	Production of saltpetre (potassium nitrate) with *Nitrosomas sp.* and *Nitrobacter sp.* in Germany
1676	Anthony van Leuwenhoek observes bacteria through a microscope
1837	Charles Cagnaird-Latour identifies yeast as causer of fermentation (one year later confirmed by Theodor Schwann and Friedrich Kützing)
1849	Industrial production of bakers yeast
1856	Louis Pasteur separates brewer yeasts from lactic bacteria
1876	Kühne creates the term "enzymes"
1881	Industrial microbial production of lactic acid (Boehringer)
1890	Development of first vaccines by Pasteur and Koch
1893	Industrial production of citric acid using *Aspergillus niger*
1897	Starting point of enzyme technology (Eduard Buchner)
1915	Patent for enzymes in washing powder
1916	Industrial fermentation process for acetone and n-butanol (Chaim Weizmann)
1928	Alexander Fleming discovers penicillin
1937	Microbial production of vitamin C
1941/42	Industrial production of antibiotics
1957	Use of *Corynebacterium glutamicum* for the production of amino acids
1972/1973	Stanley Cohen and Francis Boyer develop a procedure for in vitro recombination of DNA, using plasmid vectors
1977	First recombinant proteins from bacteria
1982	First transgenic plants and animals
1985	Development of polymerase chain reaction (PCR) by Kary Mullis
1990	Start of human genome project (HUGO)
1996	Yeast genome is completely sequenced
2000	Human genome is completely sequenced (Craig Venter)

(so-called *white biotechnology*). New tools such as screening methods and metabolic engineering, and also global analysis methods such as genomics, proteomics, metabolomeics, and bioinformatics are gradually becoming more widely available. These new instruments make it possible to reduce the time needed to develop and establish new industrial biotechnological products and processes; this was hitherto one of the major drawbacks of biotechnological, as opposed to chemical, processes. In addition, they help to develop biocatalysts (enzymes) and microorganisms which render manufacturing processes more economical and facilitate new manufacturing processes. For the first time since the beginning of the oil age in the early fifties, one is able to apply processes with economic potential in the production of basic chemicals and biopolymers based on biotechnological processes. In many cases, bioprocesses operate under milder conditions (lower temperatures and pressures, etc.) and more selectively than their competitors (chemical processes) by these means bioprocesses conserve resources and improve production processes economically and ecologically. Public debate has often emphasized the advantages for the environment; however, companies face hard economic competition so that when a biotechnological process is weighed against a classical chemical process, only the potential economic advantages can affect a shift in favour of biotechnology.

Green Biotechnology. In addition, to overcome the problems in the production both of bulk and fine chemicals but also in the production of vaccines and pharmaceuticals, the so-called green biotechnology can offer new solutions. This area of biotechnology involves the introduction of foreign genes into economically important plant species, resulting in crop improvement and the production of novel products in plants. Green biotechnology might also produce more environmentally friendly solutions than traditional industrial agriculture. An example of this is the engineering of a plant to express a pesticide, thereby eliminating the need for external application of pesticides.

Blue Biotechnology. In a very broad sense, marine or blue biotechnology can be understood as the various means of techniques of managing marine living systems for mankind's profit. The domain covered by marine biotechnology is vast and range over various overlapping disciplines, from developmental biology to chemistry of natural substances and bioprocess engineering. Not all these fields, however, are ready for practical and industrial applications. Biomass from fishing or aquaculture industry is, in fact, complex, geographically and seasonally dependent. Furthermore, many "natural substances", for which we do not know of any terrestrial counterparts, and, therefore, present an up most interest, exists only in tiny amounts in rare biological species and their exploitation is likely to call for costly synthesis procedures. Marine natural products not only display novelty but also complexity in terms of chemical structures. Isolation and structure elucidation represents only the emerged part of an iceberg. The question of the functionality of new isolated molecules within the perspective of challenging major public health and environmental problems is crucial. Likely, in this domain, ecological and evolutionary approaches should help the classical screening systems for determining the right target systems. In addition, a better understanding of the complex interactions between macro- and microorganisms is necessary to be able to use these resources for industrial purposes. Thus, more and more groups are focussing on the part of bioprocess engineering and downstream processing in blue biotechnology [3].

2. Basics in Microbiology

2.1. Microbiology – the Science of Microscopic Life Forms

Microbiology deals with microscopically tiny life forms which the resolution of the human eye (approx. 20 µm) cannot detect. Many of the single-cell microorganisms, such as yeasts, algae, or protozoa, do not reach this size. Not until the invention of the microscope (Antonie van Leeuwenhoek, 1684) was the detection, and thus also the characterization, of microorganisms possible [4].

If microorganisms are defined by their size, many varied life forms come into this category: single-cell life forms with a real cell nucleus

(e.g., algae, fungi, protozoa) and also some without a real cell nucleus (bacteria and archaea) which are of particular interest in general microbiology. Organisms with a genuine cell nucleus are termed eukaryotic organisms, those without prokaryotic organisms [5]. Today some 6500 species of prokaryotic bacteria and archaea are known, a relatively small number compared with the number of the known species of eukaryotic organisms. However, it is estimated that the number of actually living species of prokaryotic organisms is much higher, although most of them are regarded as not cultivable under laboratory conditions. Analyses of the metagenomes of the most varied habitats (total DNA assays of samples from various environments, such as forest soil, compost, pond water, etc.) have yielded estimated values of up to one billion potential species of prokaryotic organisms worldwide.

For most people, microorganisms have a bad image. The reason is not hard to find: some microorganisms can cause disease in man and animals (pathogenic microorganisms). Thanks to the achievements of *medical microbiology*, the often devastating effects of pathogenic microorganisms in earlier times have been confined due to the development of vaccines, antibiotics, etc. [6]. Nevertheless, microorganisms still represent a threat to health (for instance to people with a weakened immune system). The following are a few examples of bacteria that are pathogenic to humans: *Bacillus anthracis* (anthrax), *Bordetella pertussis* (whooping cough), *Clostridium botulium* (botulism), *Clostridium tetani* (tetanus), *Corynebacterium diphtheriae* (diphtheria), *Shigella dysenteriae* (shigellosis), *Vibro-cholerae* (cholera). The development of resistance to known antibiotics is a phenomenon that documents the variability of pathogenic microorganisms [7]. This also explains why it is necessary to promote progress in the field of combating infectious diseases with microbiological methods.

Biotechnology is closely linked to microbiology. Biotechnology uses microbiological metabolism performance to manufacture industrially relevant products. The sector with the oldest tradition of applying microorganisms for production purposes is the food industry. The manufacture of beer, wine, vinegar, bread, and cheese are early achievements of human history and pertain to the field of *food microbiology*. Microorganisms are used in the production of sausages (particularly salami), sauerkraut, and milk products (lactobacilli). In Asia, a variety of fermented food products are produced on the basis of rice and soya [8, 9].The typical aromatic properties and consistency of many food products originate from the activity of the microorganisms used. Nowadays, these organisms are generally used in the production process as starter cultures. The fermentation products are also often used as preservatives (acidification in lactic acid production by lactobacilli or alcohol production by yeasts).

The monitoring of food in the framework of quality control involves excluding undesired microbial infestation or providing evidence of it.

Microorganisms contribute towards stabilizing the global natural material cycles (e.g., carbon and nitrogen cycles). Furthermore, the waste flows produced by man are largely reintroduced into the natural material flows through the activity of microorganisms. The field of *environmental microbiology* addresses the question of how microorganisms can be utilized for the remediation of contaminated soil, water, and waste gases. Successful industrial processes have been developed and are used worldwide for wastewater and drinking water purification, brownfield clean-up, composting, and waste fermentation and also for the purification of contaminated gases [10 – 12].

Industrial microbiology, or white biotechnology, deals with the production of industrially interesting substances involving production volumes of thousands of tons. Effective production of substances requires on the one hand an efficient production strain to supply as much target product as possible in the shortest time possible. On the other hand, it needs a technical facility where the high-performance microorganisms find optimum living and, therefore, production conditions and where in addition monoseptic cultivation in large volumes is guaranteed. Bioreactors fulfill these requirements: they can be operated with volumes of up to several hundred m^3 and are equipped with automatic measurement and control systems adjusted to the growth needs of the microorganism [13, 14].

Examples of microbially produced industrial products are diverse. The list begins with microorganisms that can themselves be the prod-

uct of a biotechnological process and reach the market as starter cultures [15]. Currently the quantitatively dominant product is ethanol, of which over 24×10^6 (metric) tons are produced worldwide. Ethanol is produced with the yeast *Saccharomyces cerevisiae* and is mainly used as a substitute fuel or in admixture with other fuels. Other products include pharmacologically active agents (e.g., antibiotics, steroids, and alkaloids), bulk, special, and fine chemicals, food and feed additives, chiral intermediates, enzymes, antibodies, etc.

The total value of all biotechnologically produced substances worldwide (including biopharmaceuticals which are often manufactured with cultures of animal cells) must be in the realm of $> 100 \times 10^9$ euros annually.

2.2. Phylogeny and Taxonomy of Microorganisms

2.2.1. Definition and Survey

Taxonomy is the branch of biology which subsumes individual groups of species into a hierarchical system. For a long time, the kingdom was the highest category of creatures. Originally, a distinction was made between animals and plants. Later, the bacteria were added and then the fungi and plants were split up [16]. Finally the archaea were given their own kingdom. In recent years, genetic investigations have led to a new classification with the "*domain*" superimposed over the kingdom. Whereas in earlier times the aim was to understand and deduce relationships among microorganisms on the basis of morphological, physiological, and cytological similarities, in the last few decades genetic similarity has been the criterion used to identify relationships directly from the genetic material. Nowadays, sequence analysis of ribosomal RNA (rRNA), which was developed by Carl Woese, is one of the methods by which phylogenetic trees can be generated [17].

Probably the best-known gene in the world is the 16S rRNA (S, Svedberg unit for characterizing the behavior of sedimentation) of prokaryotic organisms. This gene is composed of around 1500 base pairs and in the course of evolution was only subjected to relatively minor changes through mutations. The reason is that ribosomes are the sites of protein biosynthesis and the molecular mechanism taking place is extremely sensitive to radical mutations. Thus, there are areas within 16S rRNA that are extremely well preserved, but also some where base exchanges have been more frequent. An evolutionary gap between two organisms can be determined from the relative similarity of different genes for the 16S rRNA of various prokaryotic organisms; this can be used as a measure of the degree of relationship [18].

Analogous to the investigations on prokaryotic organisms, the characterization of the degree of relationships of eukaryotic organisms is derived from their 18S rRNA, a molecule with approximately 2300 bases.

Besides comparing the base sequences of rRNA, the amino acid sequences of universal proteins may also be drawn on to establish relationships. This does not always involve the same branchings of the phylogenetic tree as with the comparison of rRNAs. This explains why taxonomy, which owes its motivation primarily to the potential inherent in the new molecular biology tools, is currently a highly dynamic area of science.

Today, all living organisms on earth are classified into three domains: archaea, bacteria, and eukaryota. The following representation of the manifold life forms of microorganisms adheres to this phylogenetic classification.

2.2.2. Bacteria

Bacterial cells are small, generally less than 2 μm in diameter and 2–5 μm long (there are only a few giants of 5×20 μm dimensions). The cells do not contain a membrane-enveloped nucleus; their DNA is rather a circularly closed double strand lying within the cytoplasm. The bacterial DNA contains the total genetic information of the cell. In many bacteria there are additional DNA circles, the plasmids; however, they are not required for growth under ordinary culture conditions. The ribosomes are small (sedimentation constant in the ultracentrifuge: 70 S), and their function is sensitive to various antibiotics that do not act upon the cytoplasmic ribosomes of eukaryotic organisms. In contrast to eukaryotic cells, bacterial cells do not contain organelles,

but often polyphosphates, poly(β-hydroxybutyric acid), or glycogen as storage substances (Fig. 1). Most bacteria are surrounded by a cell envelope that contains peptidoglycan (murein). Many bacteria are motile by either flagellar or gliding movements.

Classification of Bacteria According to the Phylogenetic System. Originally, the subdivision of bacteria was based on their morphology and physiology, in the last few years, however, their classification has been completely revised and established on a molecular biology level. Thus, the taxonomy of bacteria, especially the higher levels of classification, cannot yet be regarded as definitive. Some authorities believe that the degree of variance between different bacterial groups is sufficient to give them each "kingdom status" of their own. Thus, in some publications reference is made to 13 kingdoms of bacteria, in others to "phyla" instead of kingdoms.

The classification presented is derived from Bergey's Manual of Determinative Bacteriology [9], which the bacteria are subdivided into the following phyla:

- Proteobacteria
- Gram-positive bacteria
- Cyanobacteria
- Chlamydia
- Plantomyces
- Bacteroids/Flavobacteria
- Green sulfur bacteria
- Spirochetes
- Deinococci
- Green non-sulfur bacteria
- Hyperthermophiles (3 kingdoms)

Bearing in mind all the postulated, noncultivable species, the actual number of bacterial phyla (or kingdoms) is probably far higher. Estimates assume that there will ultimately be about 50 phyla (or kingdoms) of bacteria. The current phylogenetic tree, therefore, can only be regarded as a snapshot.

The bacterial phyla with the highest number of species known today are the proteobacteria, Gram-positive bacteria and cyanobacteria. Cyanobacteria are phototrophic organisms closely related to Gram-positive bacteria. Gram-positive bacteria form a group of chemo-organotrophic bacteria. The phylum of proteobacteria is the largest and physiologically most varied of all bacteria. Representatives of this phylum account for the majority of known Gram-negative bacteria of medical- and application-oriented interest [20].

Even the possibly best-known bacterium, *Escherichia coli*, belongs to this phylum. This example is used to demonstrate the taxonomic classification of an organism:

Domain:	Bacteria
Phylum:	Proteobacteria
Class:	Gamma protobacteria
Order:	Enterobacteriales
Family:	Enterobacteriaceae
Genera:	Escherichia
Species:	Escherichia coli

The binomial nomenclature is used throughout biology. Each organism has a genus name and a species name and is thus specified unambiguously.

2.2.3. Archaea

Several properties distinguish archaea from bacteria and eukaryota. Archaea are single-cell organisms mainly with a closed DNA molecule lying within the cytoplasm. They are of the same size as bacteria. Archaea have neither a cytoskeleton nor cell organelles, they are distinguished from bacteria by their lack of peptidoglycan and the different structure of their ribosomes. With over 200 species they are often found where extreme conditions prevail.

Archaea have cell walls of pseudopeptidoglycan and single-layer cell membranes formed from ether lipids with covalent bonded chains. Many species of archaea have adapted to their

extreme surroundings, hence some species prefer temperatures of over 80°C (thermophile), others live in salt waters (halophile) or in very acidic or alkaline environments (acidophile/alkaliphile) [21].

Enzymes from such extremophile organisms, which are not only found among archaea, are particularly interesting for industrial applications; indeed they seem predestined for use in industrial processes with high temperatures and salt concentrations [22]. In the area of amylases thermotolerant enzymes are already applied for starch saccharification. Moreover the enzymes used in detergents (proteases, lipases, amylases, cellulases) are active and fulfill their functions at temperatures of 60°C and above [23].

The phylogenetic system of the archaea that is valid at present subdivides the domains into the following phyla [19]:

- Euryarchaeota
- Crenarchaeota
- Korarchaeota
- (Nanoarchaeota is proposed as an additional phylum)
- Archaeota

The *Euryarchaeota* are a diverse group. This phylum comprises not only methanogenic species, which are strictly anaerobic organisms, but also strictly aerobic organisms. Furthermore a large group of hitherto noncultivable organisms belong to this phylum and similarly to that of the *Crenarchaeota*, which include both hyperthermophilic representatives and mesophilic marine species. It is only very recently that representatives of the *Korarchaeota* phylum have been cultivated successfully.

2.2.4. Morphological and Physiological Properties for the Identification of Prokaryotic Species

The properties of prokaryotic organisms as presented here permit the identification of species by conventional methods if molecular biology techniques are not available or cannot be applied. The shapes of most species are similar, and there are only a few morphological characteristics suitable for differentiation. In contrast, the diversity of metabolic features is tremendous. Prokaryotic organisms are extremely versatile. Therefore, a great number of physiological and biochemical properties have to be determined to describe and identify a species unambiguously.

Properties and description of prokaryotic organisms:

1) *Shape.*
   The majority of prokaryotic organisms are spheres, rods, or helices; these organisms are called cocci, rods, and spirilla, respectively (Fig. 2). Some organisms are encapsulated by proteins or polysaccharides, and some are combined to form packets, filaments, or consortia.
2) *Flagellation.*
   The kind of flagellation, length, type of undulation, and mode of attachment of flagellae are important characteristics of prokaryotic organisms (Fig. 3).
3) *Gram Stain.*
   The Gram stain, originally devised by CHR. GRAM (1884) to make bacteria visible in animal tissues, is a reliable and fundamental cellular characteristic by which the bacteria are divided into two parts: Gram-positive and Gram-negative bacteria. It is based on the retention or discoloration of bacteria by ethanol after a staining procedure involving an aniline dye and iodine. In Gram-positive bacteria, the dye is retained by a cell wall consisting of a multilayered network of peptidoglycan; in Gram-negative bacteria, the dye is readily washed out because the cell wall consists of only two peptidoglycan layers and a highly permeable outer membrane envelope. The basic structural differences are easily visible in ultrathin sections (Fig. 4).
4) *Endospores.*
   Endospores are highly refractile, thermoresistant stages in the life cycle of two groups of Gram-positive bacteria belonging to the genera *Bacillus* and *Clostridium*. Endospores are easily visible and tolerate pasteurization (treatment by moist heat for 10 min at 80 °C). Heating in an autoclave for 20 min at 120 °C is required to kill the spores.
5) *Need for Oxygen.*
   Many prokaryotic organisms grow only in the presence of atmospheric oxygen. They are *strictly aerobic* organisms. In contrast, *strictly anaerobic* organisms can only grow in the absence of oxygen. *Facultatively anaerobic* or-

ganisms can grow under both conditions. The last group includes aerotolerant species which tolerate but do not use oxygen. Others use oxygen if it is available. Some aerobic species are microaerophilic, i.e., they grow at low partial pressures of oxygen but not in equilibrium with air.

6) *Energy Generation.*
The production of energy, i.e., regeneration of adenosine triphosphate (ATP), occurs via three fundamental processes, namely, fermentation, respiration, and photosynthesis. The strictly anaerobic fermentative prokaryotic organisms rely only on fermentation. All strict aerobes regenerate ATP by oxidative phosphorylation with oxygen as the electron acceptor. Mechanistically, energy generation by denitrifying, sulfate-reducing, methanogenic, or acetogenic species is quite similar to aerobic respiration and is therefore designated as anaerobic respiration. All photosynthetic microorganisms contain light-absorbing pigments, such as chlorophyll derivatives and carotenoids. The processes by which ATP is regenerated are similar in respiration and in photosynthesis; both are described as electrophosphorylation.

7) *Effects of Temperature and pH.*
The majority of organisms are *mesophilic:* they grow at their maximum rate between 20 and 42 °C. *Thermophilic* bacteria and archaea reach their maximum growth rates between 40 and 80 °C. A few of them are able to grow above 80 °C and up to temperatures of over 100 °C; they are called *extremely thermophilic* organisms. The *psychrophilic* (or kryophilic) species prefer temperatures below 20 °C. Most organisms tolerate pH values between 5 and 8 but prefer neutrality; a few are acid-tolerant, acidophilic, or alkali-tolerant, alkaliphilic.

8) *Nutritional Types.*
All organisms that can use light energy for growth are called *phototrophic*. In contrast, the term *chemotrophic* denotes energy conversion by oxidation – reduction reactions that involve either fermentation or respiration. *Organotrophic* denotes the utilization of organic compounds, and *lithotrophic* the utilization of inorganic compounds (ammonia, nitrite, hydrogen sulfide, sulfur, hydrogen, carbon monoxide, iron(II)) as reductants. *Autotrophic* characterizes the ability to synthesize the majority of cellular constituents from carbon dioxide, and *heterotrophic*, the derivation of cellular constituents from organic compounds. The designations are usually combined, e.g., *Chromatium okenii* is photolithoautotrophic. Some organisms require accessory nutrients, such as vitamins or amino acids, for growth.

9) *Natural Habitats.*
The ecological habitat is the place where an organism or a population can usually be found. Examples are marine water, the sediment of a lake, fertile soil, or the intestinal tract.

10) *Symbiotic or Parasitic Relationships.*
The close relationship between two dissimilar organisms is called symbiosis. It may be favorable for both (mutualistic) or unfavorable for one (parasitic).

Figure 2. Shapes of bacteria

11) *Composition of Cellular Macromolecules.*
The description of bacteria includes the Gram type of the cell wall, the type of peptidoglycan structure, the fraction of cytosine + guanine in the DNA, the similarity index of the 16 S rRNA, and data on DNA–DNA hybridization.
12) *Antibiotic Resistance.*
The characterization of an organism may be supplemented by its pattern of antibiotic resistance.

2.2.5. Eukaryotic Microorganisms

2.2.5.1. Definition

The cells of most eukaryotic organisms are usually much larger than prokaryotic cells and have diameters of 10 µm or more [24]. They contain several structural components, compartments, and organelles. Figure 5 shows a plant cell as an example of a eukaryotic cell. The nucleus, consisting of a set of chromosomes that divide by mitosis, is surrounded by a double membrane. The DNA is associated with histone protein. Mitochondria (for respiratory energy conversion) and chloroplasts (in plants for photosynthetic energy conversion) contain a prokaryotic type of DNA and ribosomes. Cytoplasmic ribosomes are large (80 S). Endoplasmic membranes and various kinds of membrane vesicles compartmentalize the cell; they are involved in the ingestion of nutrients (endocytosis) and the production and excretion of proteins and particles (exocytosis).

An internal skeleton, the cytoskeleton, consisting of contractile protein (actin) filaments and microtubules, gives the cell its shape and confers ability to move and to transport membrane vesicles within the cell. The cells of eukaryotic microorganisms can be motile by either ameboid or flagellar movement.

Most eukaryotic cells and organisms are aerobic. Energy for growth is derived from respiration or photosynthesis.

Eukaryotic microorganisms include the protozoans, algae, and fungi. Fungi are the most relevant representatives of eukaryotic microorganisms in biotechnology and are used to produce antibiotics, secondary metabolites, and also organic acids, vitamins, etc. For this reason, fungi will be considered here in more detail.

2.2.5.2. Fungi

Fungi are aerobic eukaryotic organisms; they form a separate kingdom within the domain of the eukaryota [25, 26]. There are unicellular fungi, but the majority form filaments (hyphae), (usually 5–10 µm in diameter) and grow as masses of hyphae (mycelia). Many fungi form

fruiting bodies. The shapes of fungi are diverse, and fungi are usually identified on a morphological basis. They are much less versatile metabolically than bacteria, and metabolic properties are almost useless for identification. Fungi have cell walls that often consist of chitin or cellulose. The group is rich in species, their number exceeding 100 000. Some estimates assume that 95 % of fungi have not yet been described.

Growth and Reproduction. Fungal hyphae grow at their tip (Fig. 6). Each part of the mycelium is potentially able to grow, and a small piece of a mycelium can serve as an inoculum for growth. There are two kinds of reproduction, asexual and sexual.

A sexual reproduction occurs by spore formation, bud formation, or fragmentation. Conidiospores are formed on the tips of hyphae (conidiophores), e.g., in the genera *Aspergillus* and *Penicillium*. If the spores are formed within special vessels, the sporangia, they are called sporangiospores, e.g., in the genera *Mucor* and *Rhizopus*. Bud formation is the mechanism of asexual reproduction among the yeasts.

Sexual reproduction involves mating of two nuclei (karyogamy), zygote formation, and meiosis. It usually results in the formation of spores. In the lower fungi the zygote is usually transformed to a durant organ which after meiosis forms a sporangium. In the higher fungi, the zygote nucleus divides meiotically, and spores are formed either within a sac (*ascus*) or by budding on top of the basidia; the spores formed are called ascospores and basidiospores, respectively.

The taxonomic classification of fungi is currently under debate and different suggestions can be found. The subdivision presented herein closely follows a traditional classification und contains the following classes: basidiomycetes, ascomycetes, zygomycetes, deuteromycetes, myxomycetes.

Basidiomycetes. In basidiomycetes, the zygote enlarges to form a club-shaped cell, the basidium. The basidiospores are formed from projections of the basidium usually resulting in four spores on the tip. Most species are terrestrial fungi and live as saprophytes or parasites; many form mycorrhizas on trees. Nutrient media and methods have been developed to grow several hundred species and strains of these higher fungi, which include many edible mushrooms, in submerged culture. Some could be of interest in biotechnology.

Figure 6. Mycelium, conidiophores, and fruiting bodies of fungi

Ascomycetes. The ascomycetes are named for their formation of spores within a sac-like zygote, the ascus. With the exception of a few unicellular forms they grow as branched mycelia with open cross walls; they are coenocytic. Many ascomycetes grow on excrements of animals, i.e., they are coprophilic, whereas others are parasites on plants or insects. Asexual reproduction occurs by various kinds of conidiospores.

The order **Saccharomycetales** within the Ascomycetes comprises all yeasts. Typical yeasts, such as *Saccharomyces cerevisiae*, are unicellular. They grow either as diplonts (with diploid nucleus) or as haplonts (with haploid nucleus), such as *Schizosaccharomyces pombe*. All yeasts are able to grow on sugar substrates, and a few can even grow on alkanes (*Saccharomycopsis, Candida lipolytica*) or on methanol (*Candida boidinii*, *Hansenula anomala*). Yeasts are organisms often used in industrial microbiology.

Zygomycetes. The zygomycetes are lower fungi and comprise unicellular and mycelial fungi; they have diverse nutritional habits. They grow in water, soil, or moist habitats. There are saprophytic and parasitic species. The most important group biotechnologically is that of the Zygomycetales, which include *Mucor mucedo*, *Rhizopus nigricans*, and *Phycomyces blakesleeanus*. Several species are used for the production of vitamins, carotenoids, organic acids, and enzymes.

Myxomycetes. The myxomycetes or slime moulds grow on decaying plant tissue, form multinuclear plasmodia, and produce fruiting bodies of yellow, red, or brown color. There is not yet a consensus on the exact evolutionary affinities of myxomycetes, but these organisms constitute a well-defined, homogeneous group of approximately 900 species.

Deuteromycetes. If a fungus is incapable of sexual reproduction, it cannot be classified with either the ascomycetes or basidiomycetes, hence a third group of higher fungi was created. There are many deuteromycetes of biotechnological importance: *Aspergillus*, *Penicillium*, and *Cephalosporium*. Investigations of the 18S rRNA revealed that the majority of deuteromycetes could be assigned to the basidiomycetes and ascomycetes so that the group of deuteromycetes will possibly be abandoned in the future [27, 28].

3. Metabolism

The decisive factor for the development of a successful biotechnological production is an efficient biocatalyst. If this biocatalyst is a microbial production strain, knowledge of its metabolic capabilities is very important. Such knowledge can lead to an increase in product concentration and product variety, because one catalyst can often be used to produce different products [29].

Metabolism is generally concerned with all the events occurring within a cell that not only keep the cell alive but are also manifested in growth [30]. All synthetic reactions leading to growth are energy-consuming (endergonic) and are commonly referred to as *anabolic reactions*. In order to carry out these reactions, each individual synthesis must be coupled with energy-producing reactions of the *catabolic sequence*. Metabolism therefore consists of an intricate coupling between anabolism and catabolism (Fig. 7), whereby energy transactions and transfer mechanisms are based upon the basic laws of thermodynamics [31, 32].

Furthermore, in order to obtain a functional biosynthesis, the microbial cell must also produce a reducing agent, because biosynthesis involves the reduction of small molecules of high oxidation state to larger molecules of lower oxidation states. Both the energy and the reducing agent can be obtained from any of a number of diverse reactions depending upon the growth conditions and the genetic system available [33, 34] within the metabolism. Energy is generally dependent on adenosine triphosphate (ATP) and the reductant on nicotinamide dinucleotide NADH or NADPH.

The cell has a very sophisticated regulatory control system that avoids oversynthesis of any chemical compound, thus securing its integrity. These regulatory control systems start at the cell membrane (substrate uptake) [35] and are present throughout the pathways of catabolism and anabolism.

Figure 7. Anabolic and catabolic reactions in microbial metabolism

3.1. Microbial Systems Biology

In the future, systems biology will enable the metabolism of some microorganisms to be modeled and mapped in silico to such an extent that physiological performance and effects caused by environmental changes will be predictable. The essential prerequisites include sufficient knowledge of metabolic material flow and network analysis, reaction kinetic analysis of biochemical networks (enzyme kinetics, global metabolism regulation), global analysis of gene regulation networks (signal transduction), analysis of populationwide systems (quorum-sensing networks), and the abstraction of fundamental regulation patterns. The first such model that integrates signal transduction, gene expression and metabolism has already been introduced for the response of yeast to osmotic shock [36].

There is no doubt that such models signify great progress for microbiology and biotechnology: quantitative simulations and targeted interventions in the metabolic network ideally open up the way to highly specialized, optimized production organisms. In order to optimize specific types of metabolic performance or to accelerate desired biosyntheses, industrial biotechnology is already relying to a great extent on the metabolic engineering of microorganisms. Here, mention should be made of the synthesis of amino acids [37, 38], optimized riboflavin production in *B. subtilis* [39], and, in the case of terpenoids, yield increases by engineering mevalonate biosynthesis in *E. coli* [40]. It is likely that knowledge from systems biology will trigger tremendous progress in this application-oriented field. Moreover, strategies based on systems biology will also be important for biotechnological process development where an understanding of the complex regulatory networks of production organisms will be indispensable for process optimization [41].

3.2. Energy Production

Redox reactions are among the most important chemical reactions in living organisms. These oxidation – reduction reactions are of special importance for energy production by living organisms:

$$\Delta G^0 = n\,F\,\Delta E^0$$

where ΔG^0 is the standard free energy of the reaction, n is the number of electrons (or hydrogen atoms) involved, F is the Faraday constant, and ΔE^0 is the potential difference between the two redox systems. The simplest way to think about these oxidation – reduction reactions is in terms of electron donors and acceptors. Thus, the substrate oxidized has a specific redox potential that is at the lower end of the electrode

potential scale, whereas the final electron acceptor has a potential towards the more positive end of the scale. The difference between the two potentials corresponds to the energy obtainable in a chemical reaction between them. If the potentials of the substrate (electron donor) and of the final electron acceptor are known, one can easily determine the energy production in a microbial system (Fig. 8) [42, 43].

Figure 8. Redox potentials of various energy-producing microbial reactions

Because the potential difference between electron donor and acceptor can be significant, the energy released could produce so much heat that the cell would be damaged. In order to avoid such cell damage, the cell has an energy-release-controlling cascade system, which makes certain that energy is released only stepwise. This cascade system is referred to as the respiratory chain or the electron transport chain. It is located in the cellular membrane and is responsible for the production of energy by electron transfer involving an enzyme called ATPase (which forms or hydrolyzes ATP) [35, 44]. The ATPase also plays an important role for the transportation of substances across the membrane into the cell.

According to the chemiosmotic hypothesis for ATP production, the electron transfer chains are coupled to ATP synthesis by a proton electrochemical gradient ($\Delta\mu_H^+$) across the energy-transducing membrane. Proton electrochemical potential is a thermodynamic measure of the extent to which the proton gradient across the membrane deviates from equilibrium. This hypothesis is based on two separate proton pumps, whereby the $\Delta\mu_H^+$ is generated by electron transfer and is used to drive the second pump, involving the enzyme ATPase, backward in the direction of ATP synthesis. The final result of substrate oxidation is therefore the generation across the cell membrane of gradients of both pH (ΔpH) and electrical potential (ΔE). Both gradients exert a force on the protons extruded by the respiratory chain, tending to pull them back across the membrane. This proton motive force, $\Delta\mu_H^+$, is the key element:

$$\Delta\mu_H^+ = \Delta E - 2.303\, RT/F \cdot \Delta\mathrm{pH}$$

The numerical value of 2.303 *RT/F* is 59 mV at 25 °C.

3.3. Substrate Transport

Substrates undergoing catabolic reactions must enter the cell before catalysis can occur, because most catalytic enzymes are inside the cell. The cell membrane is a barrier for most ions and other molecules. For an ion to be transported across a membrane both a pathway and a driving force are required. Driving forces can be concentration gradients, electrical potentials, metabolic energy, or a combination of these. Four processes are known [45, 46]:

1) In *simple diffusion*, solutes move passively across the cell membrane, depending on the concentration gradient and thermal motion of the molecules (e.g., water, gases, low molecular hydrophilic compounds, organic acids in the protonated form).
2) In *facilitated diffusion*, solutes require a carrier for their transport in addition to the concentration gradient and thermal motion of the molecules. In both simple and facilitated diffusion, no metabolic energy or proton motive force is required. The energy for the transport stems from existing concentration gradients.
3) The term *active transport* is applied to a tight coupling of transport to metabolism in the ion pumps, which are central to chemiosmotic energy transduction. There are at least two

distinct classes of active transport systems: the membrane-bound and the binding protein transport systems.

4) The *group-translocation transport* system comprises processes in which the passage of the substrate across the membrane occurs simultaneously with, and as a consequence of, chemical transformation of the substrate (e.g., phosphoenolpyruvate–glucose–phosphotransferase system with most anaerobic and facultatively anaerobic bacteria). Active transport and group-translocation transport are often referred to as "primary transport", simple and facilitated diffusion as "secondary transport". The carrier systems involved can be of the "uniport", "symport", or "antiport" type.
   Many bacteria pump natrium ions out of the cell by taking in two protons per natrium ion in an antiport system. Sulfate ions, on the other hand, are only taken in by some transport systems if protons are simultaneously "symported".

3.4. Catabolism

3.4.1. Photosynthesis

Photosynthesis creates living matter out of inorganic material, replenishes the reservoir of oxygen in the atmosphere in the cases of algae and plants, stores the energy of sunlight to support the life activities of organisms, and removes carbon dioxide:

$$CO_2 + H_2A + \text{light} \rightarrow (CH_2O) + 2\,A + \text{chemical energy}$$

If A is taken to be oxygen the process is plant (or algae or cyanobacteria) photosynthesis; if it represents a sulfur atom the process is bacterial photosynthesis [43].

The process of photosynthetic energy conversion is initiated when photons are absorbed by specific molecules, such as chlorophyll. This absorption leads to an ejection of electrons, which are accepted by the compound having the lowest redox potential in animate nature, namely ferredoxin. The electrons then move through the electron transport system, and the energy is finally converted to ATP. Because the electrons return to the reaction center (Fig. 9), this system is called cyclic photophosphorylation. The reducing agent is produced separately. In plants and algae, a second photosystem exists that splits water into H^+ and oxygen, whereby the hydrogen ions reduce $NADP^+$ and oxygen is set free. In bacteria, however, such a second photosystem does not exist, and inorganic compounds such as thiosulfate are oxidized, with the electrons running through the electron transport system to the reaction center and the proton via ferredoxin to NAD^+ (Fig. 9). This is the reason why plants and algae possess mainly cyclic and bacteria noncyclic photophosphorylation.

3.4.2. Chemosynthesis

In chemosynthesis, all energy and reducing agents are obtained by catalytic reactions of organic or inorganic compounds. In the former case, one refers to *chemoorganotrophy* and in the latter to *chemolithotrophy*. In addition, three different energy modes, which depend upon the electron donors and acceptors, are distinguished: aerobic respiration, anaerobic respiration, and fermentation [47].

Organic substances are used as an energy source by the vast majority of microorganisms that live in natural environments (Fig. 10). Nature provides them with an abundance of large organic polymers. A polymeric substance consists of series of monomeric units linked together. These monomeric units can be of the same kind (e.g., cellulose, starch) or of different kinds (e.g., pectin, lignin, sucrose). Within the polymeric structure, the monomeric units can be linked in a straight chain with identical linkages or different linkages or in branched chains; moreover, they can be linked in a specific sequence or at random. The structure of each of the polymer substrates for microorganisms is very important, because the enzymes produced by the microorganisms are specific not only to the types of monomers, but also in most cases to the way in which the monomers are linked.

Since microorganisms can only take up monomers, all enzymes involved in the breakdown of polymeric substances must be extracellular. These enzymes are either membrane-bound or released into the medium. In general terms, Gram-negative bacteria accommodate these enzymes in the periplasmic space between the cell membrane and the cell wall and

Figure 9. Schematic representation of cyclic and noncyclic photophosphorylation in nature

Figure 10. Schematic representation of aerobic catabolism in microorganisms

the enzymes are thus membrane-bound, whereas Gram-positive bacteria and fungi have a tendency to release these enzymes into the medium. This is one of the reasons why extracellular enzyme studies are carried out predominantly with Gram-positive microorganisms, as well as yeasts and other fungi.

3.4.3. Carbohydrate Metabolism

Most renewable resources are carbohydrates. The principal carbohydrate that serves as a carbon and energy source for microorganisms is glucose. However, not all microorganisms follow the same route of glucose utilization. There are at least four major pathways of glucose metabolism, of which three lead directly to pyruvate:

1) *Embden-Meyerhoff* (EM) pathway, often referred to as the glycolytic or fructose bisphosphate pathway
2) *Hexosemonophosphate* (HMP) pathway, often referred to as the pentose shunt or pentose phosphate pathway
3) *Entner-Doudoroff* (ED) pathway

4) *Phosphoketolase* (PK) pathway, almost entirely specific for heterofermentative lactic acid bacteria

All four pathways of glucose metabolism have a great number of intermediates and enzymes in common. The details of these pathways can be found in many textbooks [32, 34, 48].

The EM pathway, for example, provides the greatest amount of ATP, but it does not produce ribose-5-phosphate, the important precursor for RNA and DNA biosynthesis; nor does it produce erythrose-4-phosphate, which is important for amino acid biosynthesis. Microorganisms that are capable of using only the EM pathway for glucose utilization are therefore not able to grow on simple media with glucose as the sole carbon source. They require growth factors or organic compounds (e.g., yeast extract) for growth and are referred to as fastidious microorganisms.

In contrast, the HMP pathway produces all the precursors necessary for both RNA and DNA as well as for aromatic amino acid biosynthesis, but it produces only half the amount of ATP energy. This pathway does not produce pyruvate directly. The microorganisms must therefore possess part of the enzymes of the EM pathway. It is therefore not surprising that both pathways, EM and HMP, are common combinations, particularly in facultative anaerobic microorganisms.

The ED pathway is unique, however, and has so far only been found in bacteria. Although this pathway is linked partly to the HMP pathway in the reverse direction for precursor formation, pyruvate is formed directly because of the aldolase cleavage of 3-ketodeoxy-6-phosphogluconate. The ED pathway can exist on its own and is used by the majority of strictly aerobic microorganisms. The net result is similar to the HMP pathway, although one mole of ATP can be formed only if the carbon atoms go into pyruvate instead of precursor.

3.4.4. Aerobic Processes

All aerobic microorganisms use the tricarboxylic acid (TCA) cycle as a main metabolic pathway. In this cycle, appropriate groups of enzymes catalyze a series of consecutive transformations, including oxidations, which finally result in the complete oxidation of pyruvate to carbon dioxide. The electrons and hydrogen atoms removed from the individual organic compounds are accepted by oxygen and form the other two end products, ATP and water. The tricarboxylic acid cycle, however, is not only an energy-producing cycle, but it is also responsible for the production of precursors for amino acid and antibiotic biosyntheses [49, 50]: 2-ketoglutarate and oxalacetate ions. The tricarboxylic acid cycle serves, therefore, as the central pathway for the production of energy as well as for anabolic precursors.

Under ideal growth conditions, the intermediates of the tricarboxylic acid cycle would be continuously withdrawn for anabolic reactions. Then, the formation of oxalacetate at the end of the cycle became vulnerable. Because oxalacetate is required not only as a precursor for anabolic amino acid biosynthesis, but also for the condensation with acetyl-CoA to keep the tricarboxylic acid cycle alive, the organism must have some safety device to ensure that oxalacetate is always available; otherwise the tricarboxylic acid cycle would be interrupted. The organism possesses a very fine control system for energy production and biosynthetic requirements in form of replenishment sequence reactions. Altogether, the microbial world has five enzymes at its disposal for such sequences, of which phosphoenolpyruvate carboxylase is probably the dominant: it catalyzes the formation of oxalacetate from phosphoenolpyruvate and carbon dioxide. Phosphoenolpyruvate, in turn, is the intermediate from which pyruvate is formed in the EM pathway.

This double function of the tricarboxylic acid cycle as an energy-generating cycle as well as a biosynthetic precursor-supplying cycle is very often referred to as amphibolic. This dual function, of course, must be controlled. There exists one enzyme in the tricarboxylic acid cycle, isocitrate dehydrogenase (it catalyzes the reaction: isocitrate $\rightarrow$ oxalosuccinate), which performs this regulatory control. In the case of an overproduction of ATP this enzyme is inhibited by ATP, preventing any further oxidation and ATP synthesis, until the biosynthetic steps leading to RNA, DNA, aromatic amino acids, and fatty acids have caught up and utilized the excess ATP [33].

The general scheme in Figure 11 outlines the intricate interconnections between catabolism

Figure 11. General scheme of interconnections between catabolism and anabolism (cell biosynthesis)
Ⓟ= Phosphate

and anabolism among all those precursors necessary for cellular biosynthesis. Aerobic processes in biotechnology are used to produce various products, for example, antibiotics, amino acids, and organic acids [29, 51, 52].

3.4.5. Fats and Fatty Acid Metabolism

Fats are another major group of naturally occurring compounds (see Fig. 10). The majority of fats are triglycerides, that is, fatty acids (R^1, R^2, R^3) esterified with glycerol:

These fats have to be converted into the monomeric components, the fatty acids and glycerol. This hydrolysis is carried out by enzymes called lipases. The glycerol component is converted to dihydroxyacetone phosphate, which participates in the EM pathway. The fatty acids, which vary in their carbon chain length, have to be activated by the formation of their respective coenzyme A (CoA) esters; this reaction step requires energy. These fatty-acid-CoA esters subsequently undergo cyclic oxidation, eliminating an acetyl unit at each turn. This type of oxidation is referred to as *β-oxidation*. The acetyl-CoA formed after each cycle can then enter the tricarboxylic acid cycle for the formation of energy and biosynthetic precursors.

However, this type of metabolism leading to acetyl-CoA does not produce the important ribose-5-phosphate and erythrose-4-phosphate. In order to obtain these precursors, all organisms whose metabolism leads directly into the tricarboxylic acid cycle via acetyl-CoA and not via pyruvate have to build up the carbon chain mentioned above and have introduced two pathways for this biosynthetic purpose:

1) The *glyoxylate cycle*. As mentioned earlier, overproduction of ATP inhibits the enzyme isocitrate dehydrogenase. The organism is then capable of inducing two new enzymes, isocitrate lyase and malate synthase, to circumvent the carbon dioxide-producing steps of the tricarboxylic acid cycle. This new shortcut TCA cycle leads to succinate and via glyoxylate to malate, and oxalacetate is formed despite the inhibition of isocitrate dehydrogenase (see Fig. 10).
2) The *gluconeogenic pathways*. From the oxalacetate formed, the organism is using one of the earlier mentioned replenishment sequence reactions to produce phosphoenol-pyruvate and reverses the EM pathway to glucose-6-phosphate; from there ribose-5-phosphate and erythrose-4-phosphate can be formed via the forward HMP pathway.

A great number of enzymes are common to both carbohydrate and fatty acid metabolism, which shows the economy of bacterial metabolism. The principal differences are in the control systems, which are outlined in detail in the literature, for example, [32, 34].

3.4.6. Hydrocarbon Metabolism

The metabolism of hydrocarbons has been examined in detail in the framework of environmental biotechnology in connection with cleanup of contaminated sites. Aliphatic hydrocarbons are good substrates for a large number of microorganisms. The straight-chain alkanes are more readily attacked than substituted or branched-chain alkanes. The attack occurs at either one end (monoterminal) or both ends (diterminal). The alkane is converted via the primary alcohol into the corresponding fatty acid and then via β-oxidation into acetyl-CoA as outlined previously. Methyl group oxidation incorporates one atom of oxygen; this reaction is catalyzed by a mixed oxidase system consisting of three proteins: rubredoxin, NADH-rubredoxin reductase, and -hydroxylase. For the oxidation of methylene groups, rubredoxin is replaced by cytochrome P450 and -hydroxylase by methylene hydroxylase [53, 54].

Aromatic hydrocarbon utilization follows a uniform biochemical concept. The great majority of aromatic hydrocarbons, irrespective of the number of benzene rings, converge in their oxidative metabolism to three major intermediates: catechol, 3,4-dihydroxybenzoic acid (protocatechuic acid), and 2,5-dihydroxybenzoic acid (gentisic acid):

The benzene nucleus in these intermediates is cleaved either between adjacent hydroxyl groups (ortho cleavage) or between a hydroxyl and a carboxyl group (meta cleavage). In both cases, the active incorporation of an oxygen molecule is required. Ortho cleavage, via the 2-ketoadipate, and meta cleavage, via the keto acid pathway, lead into the tricarboxylic acid cycle at the level of acetyl-CoA, succinate, or malate and fumarate. As in fatty acid metabolism, the organisms use the tricarboxylic acid cycle for energy production and require the glyoxylate cycle together with gluconeogenesis to obtain pentose for RNA and DNA precursors.

3.4.7. Amino Acid Metabolism

The aerobic utilization of amino acids follows a pattern that is very similar to the metabolism of other carbon sources [29, 49]. The only difference is the -amino group. In most cases, the amino acid is first converted into the corresponding keto acid by either cytochrome-linked oxidases, transaminases, or NAD(P)-linked dehydrogenases. The final product of the metabolism always leads to the intermediates of the tricarboxylic acid cycle. This is one of the reasons why -amino acids are able to function as the sole source of carbon, nitrogen, and energy for many microorganisms. As in fatty acid and hydrocarbon metabolism, microorganisms growing on amino acids must possess the glyoxylate cycle and the gluconeogenesis pathway.

3.4.8. Anaerobic Metabolic Processes

The breakdown, or catabolism, of organic compounds in the absence of oxygen is generally referred to as *fermentation*. The microorganisms that carry out fermentations are either facultative or obligate anaerobes. The most characteristic difference between respiratory and fermentative metabolism is in ATP energy production. Because no electron transport occurs, redox reactions of organic compounds play a major role. The number of cells obtained per mole of substrate in simple defined media is much smaller than under aerobic conditions. In addition to the cell material, large amounts of organic end products are formed, mainly primary alcohols, e.g., ethanol or butanol.

Fermentations are normally classified according to their principal fermentation products. Figure 12 summarizes the end products from carbohydrates.

The distinction between aerobic and anaerobic carbohydrate metabolism is made at the pyruvate level, because in anaerobic fermentation the organism has to substitute for the tricarboxylic acid cycle. In general the organisms are not able to produce the intermediates that serve as precursors for amino acid and protein biosynthesis. Therefore, fermentation processes cannot be carried out on simple defined media, but always require complex media if the organism is to grow and maintain its metabolism. Most of these fermentation processes are rather complex and details may be obtained from the relevant literature [32, 34, 55].

3.4.9. Single-Carbon-Compound Metabolism

A few isolated genera of microorganisms are capable of oxidizing single-carbon compounds. Microorganisms are called *methylotrophs* if they have the ability to derive both carbon and energy from the metabolism of methanol, methanotrophs if they can do the same with methane [53, 56 – 58]. Methane and methanol were the most common substrates used in the production of single-cell protein. The oxidation of methane leads to methanol and from there to carbon dioxide.

The oxidation of methane or methanol to carbon dioxide, however, does not provide the organism with any precursors for biosynthesis. These organisms therefore possess an unusual carbon assimilatory pathway. Depending upon the enzymic assemblage, formaldehyde is incorporated into ribulose-5-phosphate or into the serine pathway in order to build up the carbon chain for the biosynthesis of RNA, DNA, and all the amino acids required for protein biosynthesis. The absence of a tricarboxylic acid cycle, the presence of anaplerotic sequence reactions, and

Figure 12. Fermentation end products of carbohydrate metabolism

the glyoxylate cycle demonstrates the biosynthetic capability of these pathways.

3.4.10. Inorganic Metabolism

Some microorganisms are capable of using inorganic compounds as an energy source in aerobic metabolism or as a final electron acceptor in anaerobic metabolism (anaerobic respiration). Both of these are combined in nature in the sulfur cycle and the nitrogen cycle, [32, 34].

Sulfur Cycle. Under anaerobic conditions, sulfate or thiosulfate can be reduced to sulfide by sulfate-reducing bacteria. Such processes occur mainly in water-logged soils or stationary estuaries rich in organic matter, and can cause serious corrosion of iron and steel pipes in the soil. Hydrogen sulfide is an extremely toxic product. If the soil or estuaries are supplied with oxygen, hydrogen sulfide can be reoxidized to sulfate by aerobic sulfur-oxidizing microorganisms, for example, thiobacilli. The reoxidation of sulfur or sulfide to sulfate is a microbial process of considerable biotechnological significance. It not only acidifies the soils and thus makes plant growth possible, but the sulfuric acid formed can also be used for ore leaching processes. Sulfuric acid can form soluble sulfates with a wide range of metals and by leaching old mining dumps it helps concentrate these for further utilization of the ore. Such ore leaching processes have led to a vastly improved mining industry and increased the economy of ore mining.

Nitrogen Cycle. Nitrogen is the most abundant gas in the atmosphere. Nitrogen-fixing organisms are capable of converting nitrogen into nitrogen compounds that are acceptable to plants. Nitrogen-fixing microorganisms can be divided into free-living (cyanobacteria, *Clostridium, Azotobacter*) and symbiotic (*Rhizobium*). The last group in particular may become of great biotechnological importance, because they live in association with legume plants and provide these with the necessary nitrogen source even in nitrogen-starved soils, thus eliminating the need for large amounts of nitrogen fertilizers. The nitrogen-fixing organisms convert nitrogen to ammonia, which then can be oxidized by chemolithotrophs (*Nitrosomonas* and *Nitrobacter*) via nitrite to nitrate. This conversion of nitrogen to nitrate is referred to as *nitrification*. The reverse reaction, called *denitrification*, is an anaerobic process in which the nitrate or nitrite serves as electron acceptor. The product of denitrification is nitrogen gas. Nitrification and denitrification are important process steps in biological wastewater cleaning.

The **chemolithotrophs**, however, face an energy problem. The redox potential of the inorganic compounds used as electron donors is well

above that of the NAD/NADH couple that is required as reducing agent for biosynthesis. Since the electrons can only enter the redox system at the cytochrome level, electron transport must be reversed to obtain NADH. In photosynthesis, this reversal can be carried out by the reaction center of the photosynthetic apparatus, but in chemosynthesis the reversal has to occur with energy input from the oxidation of the inorganic source. It is therefore not surprising that such organisms grow much better in the presence of organic material, which they are able to assimilate directly, thus obviating the reductive biosynthesis and consequently the need for reductant formation.

3.5. Biosynthesis

The microbial cell consists of five major types of macromolecules: proteins, polysaccharides, lipids, RNA, and DNA [32, 34]. These macromolecules are built up from relatively few monomers, which the cell has to provide or to synthesize: amino acids, sugar phosphates, fatty acids, ribonucleotides, and deoxyribonucleotides.

Microorganisms are divided into two groups: *autotrophs*, which are able to produce all their cellular requirements from carbon dioxide as the sole carbon source, and *heterotrophs* – the majority of microorganisms – which produce the cellular material from organic compounds. Photo- and chemolithotrophs use ATP and the reducing power produced by photosynthesis and/or oxidation of inorganic substrates to reduce carbon dioxide to cellular material. The pathway for carbon dioxide reduction is referred to as the Benson-Calvin cycle. The actual carbon dioxide fixation reaction is catalyzed by ribulose-1,5-bisphosphate carboxylase; the primary product of this reaction is 3-phosphoglycerate, which leads to glyceraldehyde-3-phosphate, a member of the EM pathway:

$$\begin{aligned} &3\,CO_2 + 9\,ATP + 6\,NADH_2 \\ &\quad \rightarrow \text{glyceraldehyde}-3-\text{phosphate} \\ &\quad \rightarrow + 9\,ADP + 8\,P_i + 6\,NAD^+ \end{aligned}$$

From glyceraldehyde-3-phosphate, these organisms are capable of producing the important pentoses, trioses, and the dicarboxylic acids required for macromolecular biosynthesis [46, 47].

3.5.1. Amino Acids

About twenty -amino acids are required for the biosynthesis of the numerous types of proteins that provide the catalytic capability of the microorganisms. These amino acids are produced from the following precursors:

Erythrose-4-phosphate	→ tyrosine, tryptophan
Phosphoenolpyruvate	→ phenylalanine
Ribose-5-phosphate	→ histidine
3-Phosphoglycerate	→ serine, glycine, cysteine
Pyruvate	→ alanine, valine, leucine
2-Oxoglutarate	→ glutamic acid, glutamine, arginine, proline
Oxalacetate	→ aspartic acid, asparagine, methionine, lysine, threonine, isoleucine

The most important amino acids are glutamic acid and glutamine, which figure in transamination reactions during biosynthesis. Therefore, the availability of these two amino acids is vital for protein biosynthesis. The detailed pathways can be found in the literature [32, 34, 46].

Theoretically, each of these -amino acids can be produced commercially by microorganisms, some are already produced, but some practical problems remain to be solved for some of them [49].

3.5.2. Lipids

Most of the fatty acids that occur in lipids contain 16 or 18 carbon atoms and are saturated or unsaturated with one or more double bonds. Acetyl-CoA is the only precursor for the biosynthesis of all fatty acids. In order to differentiate between fatty acid catabolism and fatty acid biosynthesis, the organisms employ CoA activation in the former and an *acyl carrier protein* (ACP) in the latter. The C_2 units are added to the acetyl-ACP in the form of malonyl-ACP. Once the required chain length is reached, ACP is hydrolyzed and the appropriate fatty acid is formed. Unsaturated fatty acids are generally formed by dehydration of a hydroxy fatty acid.

The fatty acids are then esterified with glycerol, which is readily available from dihydroxyacetone phosphate, a member of the EM path-

way. Finally, triglycerides are formed. The introduction of a phosphate group gives a phosphatidic acid and a whole range of phospholipids. If the phosphate group in the phosphatidic acid is replaced by a carbohydrate, glycolipids are produced [32, 34, 46].

3.5.3. RNA and DNA

Ribonucleotides consist of a purine or pyrimidine derivative, ribose, and phosphate groups. A purine or pyrimidine base attached to a ribose is referred to as a ribonucleoside; if a phosphate group is attached to this ribonucleoside it is called a ribonucleotide. The most important pyrimidine derivatives are uracil, cytosine, and thymine. The most important purine derivatives are adenine and guanine. The biosynthesis of pyrimidines and purines starts at the ribose-5-phosphate level, which also represents the ribose in the nucleotide. The RNA consists of ribonucleotides. Reduction of the ribonucleotides leads to deoxyribonucleotides, the building blocks for DNA biosynthesis [44, 46].

3.6. Regulation

The microbial cell possesses a complex of catabolic and anabolic capabilities with many interconnected pathways. The cell is required to maintain balance among the various parts of this extremely complex network of reactions [32, 34, 44, 46, 48]. The cell therefore has developed very intricate and refined devices to streamline its economy.

Regulation can either be manifested in the enzyme synthesis or in the enzyme activity. Induction and repression of enzyme synthesis occurs at the genetic code, whereas feedback inhibition simply regulates the activity of the enzyme. The importance for biotechnology is to realize that the first type of regulation is concerned with substrate, catabolite, and end product inhibition, whereas the second mainly involves a transitional end product inhibition.

More than one enzyme usually is required to channel a substrate into intermediary metabolism. The substrate can therefore be responsible for a coordinate or sequential induction of enzymes. This activity of the cell normally occurs during the lag phase of growth and can be reduced to almost zero by preculture conditions.

A much more complicated regulation is catabolite repression, which is mainly manifested in the so-called *diauxie phenomenon*. The latter is biphasic growth in the presence of more than one carbon source in the medium. In this reaction the organism takes up only one substrate at a time and the presence of this particular substrate represses the enzyme system that is responsible for the metabolism of the other substrate. This repression occurs at the operon level and occurs as soon as the concentration of the first substrate becomes very small.

Enzyme synthesis can also be inhibited by end products within a short period of time. For example, if the medium contains any α-amino acid, the organism would use this amino acid directly instead of producing it. The added amino acid therefore represses the synthesis of each enzyme in its synthesis pathway.

In addition to the regulation of enzyme synthesis, the cell must also adjust the *activity of enzymes* to its metabolic requirements. If a monomer is synthesized in larger amounts than needed for polymer synthesis, it is not necessary to stop the synthesis of the enzyme completely, but it suffices to reduce the activity of that particular enzyme. This fast control action is referred to as *feedback inhibition*. The target enzymes for feedback inhibition are called allosteric enzymes.

4. Metabolic Engineering

The term *metabolic engineering* refers to the genetic optimization of prokaryotic or eukaryotic cells that are used in industrial fermentation processes. In these processes, they are utilized for the economically production of proteins or other fine chemicals. Bailey [59] firstly introduced the definition of metabolic engineering in 1991 as "the improvement of cellular activities by manipulation of enzymatic, transport, and regulatory functions of the cell with the use of recombinant DNA technology." However, one of the early examples of successful genetic engineering of a living organism for production purposes, namely the production of human insulin in *E. coli* cells, had already been described

quite some time before a name was given to this new direction of science.

According to CAMERON and TONG [60], there are five categories of metabolic engineering that are grouped with respect to the objective of the genetic modification:

1) Improved production of chemicals already produced by the host organism.
2) Extended substrate range for growth and product formation.
3) Introduction of new catabolic activities for the degradation of toxic materials.
4) Production of chemicals that are new to the host organism.
5) Modification of cell properties, for instance, to make them more resistant to the production conditions.

The process of metabolic engineering is most often described by a circle of elementary steps that have to be performed once or several times. This circular process is demonstrated in Figure 13.

Figure 13. Schematic illustration of the elementary processes of metabolic engineering

The elementary processes are

– *Analysis* of the organisms with respect to the Proteome and/or metabolome
– *Design* of a genetic modification that improves/allows the synthesis of the compound of interest
– *Production* of a modified strain
– *Fermentation* and production

Depending on the task at hand, one enters the engineering cycle at different entry points. When, for instance, an organism should be modified to express a recombinant protein, the first step is to design and create the DNA sequence that codes for the protein in an appropriate vector system. Thus, one will enter the cycle at the *design* level. The same is true when an existing metabolic pathway should be extended in the way that the original end product of that pathway is metabolized to a compound of interest. However, when an existing metabolic pathway shall be used to produce a given compound in high yields, one will have to start by analyzing the metabolic situation and the metabolic fluxes in order to identify targets for genetic engineering. In this case, one will enter the cycle at the *analysis* level. In particular in the latter case, it is often necessary to go through the cycle of metabolic engineering more than once, since complex metabolic networks within living cells often require several genetic modifications to provide the compound of interest in improved quantities.

Metabolic engineering is to a high degree dependent on novel developments and improvements in chemical analytics as well as molecular biology. In both disciplines, the last decade has brought about powerful new technologies – such as protein and DNA chip technology to mention only two – that provided considerable progress in metabolic engineering. For further information, the interested reader is referred to the reviews by NIELSEN [61] and OSTERGAARD [62] and the website of a scientific journal that is exclusively devoted to this research area (www.apnet.com/mbe).

The following paragraphs will discuss in more detail the three elementary processes of metabolic engineering, analysis, design, and production of a modified strain. Fermentation will be addressed in other chapters of this series. (→ Ethanol, Chap. 5, → Antibiotics, Chap. 5)

4.1. Analysis of the Transcriptome, Proteome, and Metabolome

The bottleneck of all of the traditional methods of transcriptome and proteome characterization is the limitation to an analysis of just a few samples at a time. While conventional methods are confining themselves to the examination of single genes, a DNA or protein chip experiment

delivers a complete gene or protein expression pattern of the cell. The high degree of parallelization realized in biochips is the great advantage over classic molecular biological approaches.

4.1.1. Gene Expression Analysis using DNA Microarrays

In the past few years, the complete DNA sequences of a number of different microorganisms have been determined and can be exploited to optimize strains as well as recombinant protein production. Strain optimization involves measurement of genomewide mRNA levels in wild-type and mutant strains using DNA microarrays (Fig. 14) Furthermore, microarray analysis can help identifying previously unknown genes required for recombinant protein production.

Bioprocess optimization using microarrays entails metabolic control analysis, modeling, and molecular biology to create new mutants and strains with an, for example, optimized protein production rate. Recombinant protein expression exerts a metabolic burden on the host cell, whereby stress response mechanisms are triggered on different levels. Microarrays allow the investigation on a genome scale, which enables the qualitative and quantitative characterization of the burden on host cell metabolism. Thereby, a better understanding of the impact of recombinant protein production can be achieved by using the generated "snapshot" of the actual cellular composition and activity. Additionally, the knowledge of the interaction of host cell metabolism with recombinant protein production is improved and contributes to process optimization.

Chip Technology. Alongside metabolome analysis, analysis of various components of the proteome, the transcriptome or the genome will become increasingly valuable. New biosensors known as biochips will be required. DNA chip technology has already opened up new ways of studying disease in more depth and identifying far more possible targets. A DNA chip is an array of synthetic DNA sequences representing different genes. Up to now, membrane and immune biosensors are used to analyze substances of the metabolome. One important goal in chemical and biological sensing is the sensitive detection and selective identification of biochemical discrete compounds (carcinogens, metabolites, proteins, etc.) or living systems (bacteria, viruses, or related components) at low levels in complex biological matrices, tissues, and blood. In the future, it will be indispensable to analyze compounds of the genome and the proteome. Therefore, new formats of biosensors, so called biochips, have to be developed. Such biochips or microarrays can be used for identifying genes as well as changes in their activity. Furthermore, these biochips allow the simultaneous detection of several disease endpoints using different bioreceptors such as DNA, antibodies, enzymes, or cellular probes.

The high parallelization degree of biochips is a great advantage over classic molecular biological methods. While conventional methods are confining themselves to the examination of single genes, a DNA chip experiment delivers a complete gene expressions pattern of the cell. DNA microarrays can be used for the purpose of monitoring expression levels of thousands of genes simultaneously. Furthermore, biochips can solidly simplify and accelerate a number of long and expensive diagnostic methods. Additionally, gene expression analysis across various biological conditions, cell cycle states, tissues, and subjects may help identify differentially expressed genes. This type of information is a valuable pinpoint in the investigation of biological processes and functional disorders. Recapitulating, DNA chips provide a format to profile complex diseases and discover novel disease-related genes. Applications for this technology include gene expression monitoring, mutation detection, metabolic engineering, drug development, tailor made therapeutics, SNP research, GMO detection, and high-throughput screening, among others. They have a profound impact on biological research, industrial production, medicine and pharmacology and will be used as the biosensors of the future [63 – 67]. For the understanding of biological systems with up to 30 000 genes, the measurement of RNA levels for a complete set of transcripts of an organism will be necessary. The use of glass slides as medium enables high spot densities on microarrays (up to 10 000 spots per slide). A DNA chip experiment works by hybridizing all of the gene probes on the chip with the nucleic acid target to be tested. cDNA labeled with fluorescent tags is used, produced by

Figure 14. Interaction of labelled target molecules with probe molecules on a glass array

reverse transcription of RNA from the sample to be analyzed. Hybridizing a sample of nucleic acid with many complementary gene probes in parallel on a DNA chip produces a hybridization pattern with corresponding hybridization intensity. DNA chip technology therefore enables large numbers of genes to be screened simultaneously, giving a comprehensive, detailed picture of changes in gene expression, shedding light on complex regulatory interactions.

4.1.2. Fabrication of DNA microarrays

There are three primary technologies used presently in automated microarray fabrication including photolithography, ink-jetting, contact printing, and derivatives thereof. Each of these technologies has specific advantages and disadvantages in microarray manufacturing. The photolithographic approach relies on the in situ synthesis of 25mer oligonucleotides using photomasks. This means that each probe is individually synthesized on the chip surface. Photolithography was developed by Fodor et.al. [68] and commercialized by Affymetrix (Fig. 15). In contrast, the ink-jetting and contact printing methods attach presynthesized DNA probes to the chip surface. While the in situ probe synthesis necessitate expensive and sophisticated equipment the contact and noncontact spotting methods made DNA chips affordable for academic research laboratories. Since 1996, many DNA arrayers have become available and the self spotted glass slide DNA arrays are today the most popular format for gene expression profiling experiments.

Figure 15. Microarray fabrication using an Affymetrix 427 arrayer

4.1.3. Proteome Analysis using Protein Microarrays

The utilization of protein biochips for the Proteome analysis offers a number of alternatives and advantages in metabolic engineering. Protein microarrays make use of technological innovations and enable the proteome analysis in

miniaturized test formats, thereby promising significant advantages such as an improved analytical speed, a better separation efficiency, reduced sample/reagent consumption, contamination reduction and reduced costs. Protein microarrays consist of bound antigens or antibodies as capture molecules for detecting proteins in a complex mixture. They provide a huge potential for monitoring protein expression and protein profiling.

Although the basic construction of such protein microarrays is similar to DNA microarrays, the more delicate nature of protein structures has hindered the development of such devices for the analysis of proteins for a long time. This is due to their more complex coupling chemistry, the instability of the immobilized protein and the far weaker detection signals. In principal, microarray technology enables both, the probing of the genome and the proteome. Today, protein chip technology focuses basically on the understanding of molecular pathways which allows conclusions concerning the molecular diagnostic, the drug discovery, and metabolic engineering applications. These interferences can be done because of the capability of protein microarrays to analyze the protein function of a whole genome level [69 – 73]. The results of such high- throughput screening approaches can change our fundamental understanding of the cellular processes of life on the molecular level. However, gene expression analysis does not sufficient enable a reliable prediction of the function of a protein. Monitoring protein interactions is an extremely complex matter since the proteome is the quantitative representation of the complete protein expression pattern of a cell under accurately defined conditions. The proteome represents the protein equivalent of the genome. In contrast to the genome which is determined by the sequence of its nucleotides and therefore static, the proteome represents an extreme dynamic object which is influenced by many parameters. Not all genes will be switched on at the same time in a cell and the sensitive balance between protein synthesis and protein degradation can vary widely under different metabolic conditions. Consequently, a repeated analysis of the proteome will be successful only under exactly defined conditions, for example, cell culture conditions. In practice, this proves to be very difficult since conditions to which the cell severely reacts are often unknown. However, the sensitive dependence of most different parameters offers the possibility of applying specific small changes of the protein expression pattern in order to create sensitive biosensors.

Ideally, the analysis of the proteome delivers the currently available set of all proteins, if there is a way to maintain the quantitative relations of all proteins during the analysis. Such data cannot be obtained with classical molecular biology since no strict connection between the amount of mRNA and the amount of protein exists. Parameters such as mRNA stability, posttranslational modifications, protein degradation, and others consequently prevent a statement over the currently available amount of protein. However, this information is of utmost importance making a high throughput analysis necessary. One attractive method is the use of protein microarrays. Genomewide screens for protein function are of biological importance for many applications:

- Analyzing protein expression profiles
- Monitoring protein-protein interactions
- Identifying protein posttranslational modifications
- Screening the substrates of protein kinases
- Examining the protein targets of small molecules
- Proteomic analysis as a function of bioprocess cultivation conditions

4.1.4. Metabolome Analysis and Metabolite flux analysis

In order to improve a given strain of microorganisms or even more complicated a eukaryotic cell line that is used in a biotechnological production process, it is not only necessary to analyze gene expression patterns or the proteome. Analysis of metabolic turnover is central for recognizing possible targets for genetic engineering. Metabolic turnover comprises a large number of biochemical reactions. For instance, in the well-examined yeast *Saccharomyces cerevisiae*, about 1500 biochemical reactions have been estimated involving more than 850 metabolites and cofactors [74]. Since in most of these reactions there is more than two educts and more than one product, not to speak of the necessary cofactors, the metabolic turnover represents a complex network of biochemical reactions, also referred to

as the metabolic network. The concept of isolated metabolic pathways such as glycolysis, citric acid cycle, or urea cycle as presented in most biochemical textbooks is therefore somewhat misleading since it indicates that these pathways proceed independently. However, they are all interconnected and represent a huge interdependent network that can activate or slow down individual branches. Control over the activity of individual metabolic branches can be exerted on the levels of transcription, translation, protein-protein interaction, or enzyme activity regulation, which adds another level of complexity. According to Nielsen [77] it is therefore necessary to analyze the metabolic network in three instances (*metabolic pathway analysis*) in order to fully oversee the metabolic activities in a living cells, which is considered as a prerequisite for a rational optimization of the production strain:

- Network structure (pathway topology).
- Quantification of fluxes through the branches of the network.
- Identification of control structures.

Much work has been done in the past in biochemical laboratories around the globe to identify the metabolic network structure at least for the more well-known microorganisms – in particular when they are of industrial importance. Thus, very often the presence of a certain metabolic pathway can be deduced from the available literature. The most powerful approach to identify a certain pathway when no information is available is called metabolic labeling. Here, the organism is fed with ^{13}C-labeled glucose (or any other appropriate fundamental metabolite) and after a given time that is allowed for metabolization the labeling pattern of other intracellular components is identified and reports on the metabolic pathways involved. From the analytical perspective, analysis of the metabolite pattern is most often done by GC-MS (gas chromatography coupled to mass spectrometry) but also by NMR (nuclear magnetic resonance). Later on, biochemical assays addressing the activity of certain key enzymes can be used to confirm the presence of a certain pathway and dig out the cofactor requirements for the individual steps within the pathway. Pathway identification just by enzyme assays is possible, however, very tedious and time consuming.

Flux Analysis. Once the network topology has been identified, it is necessary to learn about the fluxes through each of the network branches. This kind of analysis requires experiments as well as mathematical modeling. The most important concept behind flux analysis is referred to as *metabolite balancing*. According to this, the concentration of each metabolite is stationary inside the cell or in other words: the generation rate of a given metabolite in one metabolic pathway (v_+) equals the rate of its onward reaction through the sum of all downstream metabolic pathways (v_-). Thus, for a given metabolite the corresponding material balance can be described as

$$v_{+1}+v_{+2}+v_{+3}+\ldots+v_{+i}=v_{-1}+v_{-2}+v_{-3}+\ldots v_{-i}$$

Such balances are established for all relevant metabolites, such that a set of algebraic equations results that describe the flux of molecules through the different branches of the metabolic network. When some of the fluxes are experimentally determined, the remaining fluxes can be deduced mathematically from this set of equations. The beauty of the metabolic balancing approach is its simplicity. But reliable predictions can only be obtained when the cofactor (NADH, NADPH, . . .) balances are also known which means that all the pathways that generate or consume any of these cofactors have to be considered in the formalism. Feeding the organisms with ^{13}C-glucose in combination with a molecular analysis of the resulting metabolite labeling downstream of glucose provides, however, an easier solution. From the labeling pattern of all metabolites it is possible to set up equations for the balances of individual carbon atoms. Thus, the number of equations describing the overall system increases the number of constraints for the solution and thus, makes balances of cofactors unimportant.

The final step in analyzing the metabolic network is to identify the regulatory mechanisms that control the fluxes through each of the branches [75, 76]. It is very obvious that detailed knowledge about flux control might immediately identify possible targets of metabolic engineering, for instance, to redirect the metabolic flux away from a pathway that does not lead to the desired product or consumes precursors. In order to understand flux control, it is necessary to study the regulation of the enzymes

that are active around the branching points of the metabolic network [77]. Here the regulatory instances can be found at several hierarchical levels as mentioned earlier in this chapter. The expression level of a given enzyme or any of its regulatory proteins may be controlled on the level of transcription, RNA processing, or translation. DNA and protein chip technology, as described above, provide powerful approaches to unravel whether any control occurs on the level enzyme expression. Finally, allosteric control over enzyme activity introduces another level of metabolic fine-tuning. The kinetic properties of an enzyme like, for instance, its affinity for the substrate molecules, the maximum substrate turnover rate and its sensitivity for product inhibition have to be characterized by biochemical assays. When these information and the current concentrations of the relevant metabolites are available, it should be possible to predict how the fluxes through individual branches of the metabolic network will change when the activity of one enzyme is altered by genetic engineering or when the feeding situation is changed.

However, it should be emphasized at this point, that due to the enormous complexity of the metabolic network and all its regulatory instances, it is very difficult to predict all metabolic consequences induced by just one genetic modification. Thus, it may be necessary to completely analyze the metabolome of the modified strain and – if the results are not satisfactory – go through one or several more rounds of metabolic engineering as sketched in Figure 13. This is particularly relevant when the organisms respond to alteration of their genetic make-up by opening up metabolic side pathways that are silent in the wild-type strain.

4.2. Design and Production of Genetically Optimized Strains for Production – In Vitro Mutagenesis

In order to generate genetically modified organism that might be superior to wild-type strains for production purposes, there are basically three major options:

A) Introduction and expression of a gene that is not originally expressed by the organism or only in small copy numbers
B) Silencing of a gene that codes for an enzyme or regulatory protein which should be switched off or reduced in expression level
C) Modifying an existing gene – and hence the coded protein – that is expressed by the organism of interest, for instance, to alter the substrate specificity of an enzyme or engineer its catalytic performance

In all three cases, the most suitable target for genetic manipulations is cloned DNA that can be handled and tailored in the well-defined environment of a test tube without the complexity of an entire organism around, in particular the cellular membranes that may hinder the accessibility of the various reagents. Cloned DNA is usually handled in form of plasmid DNA. A plasmid (cyto*plasm* + chromat*id* = *plasmid*) is a circular piece of double-stranded DNA that is autonomously replicated in bacteria and may even be exchanged between them. Plasmid DNA occurs also in wild-type strains since they are regular extrachromosomal genes that can be easily shared between certain bacteria. Many molecular tools have been developed that are specifically designed to work with plasmid DNA in vitro. A particular family of plasmids, the so-called *Expression plasmids* or *expression vectors* as the more general term, additionally contain the necessary nucleic sequences to initiate transcription (promotor) and translation of a gene that has been correctly inserted into the plasmid – instead of multiplication only. Expression plasmids for prokaryotic cells differ from those for eukaryotic cells [78]. The three different strategies to alter gene expression in more detail:

A) When a new gene should be introduced into an organism or the expression level of an existing one should be increased, this particular gene has to be cloned in a suitable expression vector controlled by an appropriate promotor that ensures a sufficiently high copy number of mRNAs and hence protein. The production of human insulin in *E. coli* is a famous example for the production of a recombinant eukaryotic protein in a prokaryotic organism.
B) When an existing gene should be silenced or reduced in activity, there are several experimental strategies. Today the most promising technique is RNA interference (RNAi), a process by which double-stranded RNA si-

lences gene expression. By transfecting cells with small interfering RNAs (siRNAs) with 100 % homology to a target mRNA sequence, a specific knock-down of the corresponding protein can be achieved. Bound by an RNA-induced silencing complex (RISC), the siRNAs induce the degradation of their homologous mRNA molecules in the cell, thus the protein expression level decreases. RNAi is a reverse-genetics approach to identify gene function by altering the phenotype of a cell [79 – 82].

C) Until the middle of the last century, traditional biotechnology concentrated on elucidating new metabolic pathways and improving the strains used for the production of antibiotics and other useful natural products, usually by exploiting random mutagenesis and selection. Later in the 1980ies, biologists began to improve strains through metabolic engineering, that is, through the modification of single metabolic pathways by means of *targeted* or *site-directed* genetic changes. The two different approaches – random or site-directed mutagenesis – to improve the genetic make-up of an organism are still applied today and shall be summarized here. However, throughout the last years progress in molecular biology has provided a pool of experimental approaches for targeted genetic changes that are way too many and multifaceted to be reviewed comprehensively. Thus, only a few principles can be discussed here, and are confined to the best-known models of genetic research, the bacteria. The interested reader is referred to other chapters of this series or the literature on molecular biology for more detailed and organism specific information [83, 84] (→ Genetic Engineering).

4.3. Random Mutagenesis, Isolation and Selection of Mutants

Spontaneous Mutants. In bacterial populations, mutational events occur at certain rates without experimental treatment. These spontaneous mutations, which result in mutants, are due to errors that occur during DNA replication. The frequency of spontaneous mutations in a bacterial population varies from gene to gene and species to species and may involve 10^{-2} to 10^{-11} of the total cell population. The spontaneous mutation rate (probability of a mutation per cell and generation) for a gene is about 10^{-5}, and for a pair of nucleotides it is 10^{-8}. The number of reversions (or functional back-mutations) is of the same order of magnitude.

Induction of Mutations. The mutant frequency can be considerably increased by treatment of the cells with chemical, physical, or biologic mutagenic agents. Three classes of mutants can be distinguished with respect to their genetic structure: 1) replacement of one base pair by another, e.g., AT by GC; 2) a base pair can be inserted or eliminated; 3) several base pairs, DNA fragments, or even genes can be lost (deletion), change their position within the chromosome (transposition), or be interrupted by insertion of foreign DNA (insertion). Class-1 mutants, called point mutants, revert readily to their original structure.

Various chemical agents are in use to induce mutations [85, 86]:

1) *Incorporation of Base Analogues.*
Base analogues are antimetabolites. Some are sufficiently similar to the natural purine and pyrimidine bases that they are taken up by the cells and incorporated into DNA during replication. They are able to fulfill their functions, but tend to bind a wrong counterpart during replication, thus introducing a wrong base pair and causing a point mutation.
2) *Chemical Change of Bases.*
Several mutagenic agents effect a chemical change in a base and thus cause an error in replication. For example, treatment of cells with nitrite results in the de-amination of adenine, guanine, and cytosine, and consequently in mispairing. Alkylating agents, such as ethyl or methyl methanesulfonate, ethyleneimine, nitrogen mustard, and *N*-methyl-*N*-nitro-*N*-nitrosoguanidine (MNG), belong to the most effective mutagenic agents. Acridine dyes (proflavin) function by intercalation and result in insertions or deletions of single base pairs.
3) *Irradiation.*
UV irradiation mainly affects pyrimidine bases and results in replication errors.
4) *Transposon Mutagenesis.*
By conjugation, transposon-containing plasmids (Tn elements) can be transferred from

an appropriate donor bacterium to the bacterium to be mutagenized. Transposons are DNA fragments that tend to "jump" to various positions in the DNA sequence of the chromosome or plasmid. Their insertion interrupts genes and results in insertion mutants.

The changes in the DNA described above involve an alteration of its base sequence, called a premutation. Subsequently, the mutant character has to be expressed in the phenotype of the cell. About 10–20 growth cycles may be required for nuclear segregation, dilution of enzymes, starting or stopping the synthesis of enzymes, and other functions.

4.4. Types of Mutants and Selection Principles

A mutation is a rare event, and the number of mutants in a population is small. Many thousands of Petri dishes would have to be inspected and many millions of colonies (clones of single cells) would have to be examined to recognize and isolate a mutant if there were not a selection (enrichment) procedure for increasing the number of the desired mutants within the population. Enrichment is achieved either by killing part of the parent cells or by growth under conditions that confer growth advantage to the mutant cells. There are many means for enriching mutants. In fact, designing strategies to select mutants is one of the most difficult and demanding arts of the microbiologist, and each type of mutant requires a special trick.

The recognition of mutants poses another problem. Mutants that have lost or gained pigment, colony size or characteristics, or that have become resistant to toxic compounds or bacteriophages can be easily detected in a lawn of parent cell colonies. Some mutants show up after addition of indicators. The detection of auxotrophic mutants requires comparison of growth on two different nutrient media. One tries to recognize mutants on an agar plate and to avoid laborious test tube assays of thousands of isolated cell clones. There are, however, many mutant types that require these efforts.

4.4.1. Auxotrophic Mutants

If the mutation has affected the ability to synthesize, for example, the amino acid leucine, the mutant will require leucine in the nutrient medium. A mutant that is auxotrophic for leucine (leu^-) can be recognized by comparison of its growth on two agar plates, one with and the other without leucine. While the phototrophic parent type (leu^+) will grow on both plates, the auxotrophic leu^- mutant will grow only on the supplemented agar.

The enrichment of auxotrophic mutants can be achieved by application of agents such as penicillin that kill only growing cells and leave non-growing cells unimpaired. If the population of parent cells and rare leu^- mutants is grown on a minimal medium (lacking leucine) only the parent cells will grow and after the addition of penicillin will be killed within a few hours. The mutants and some parent cells will survive and the mutant fraction is increased by a factor of 10^4 to 10^6. Another method involves the principle of "lethal synthesis." Growing cells will, for example incorporate radioactive phosphate or antimetabolites and will be killed while the non-growing mutants will survive.

4.4.2. Regulatory Mutants

Some mutants, which in contrast to the parent type form a biosynthetic enzyme constitutively, can be selected directly on the agar plate. For example, if an antimetabolite is added to the agar, the parent cells will incorporate it into their protein and stop growing. Mutants, however, that overproduce the normal metabolite because of overproduction of the biosynthetic enzyme will not incorporate the antimetabolite; they will grow, and sometimes even show their regulatory defect by excreting the metabolite, thus initiating secondary growth of the parent cells in the surroundings of the mutant colonies. Some procedures for the selection and recognition of mutants are listed in Table 2.

4.4.3. Other Selection Methods

Various other methods can be used to separate mutants from their parent cells. Because some

Table 2. Procedures for selecting and recognizing various mutants

Kinds of mutants	Selection or enrichment procedure	Recognition of mutants
Mutants resistant to inhibitors, antibiotics, toxic compounds, or bacteriophages	about 10^8 cells spread on a nutrient agar medium containing the inhibitory or killing agent.	only the desired resistant mutants able to grow.
Auxotrophic mutants that require accessory nutrients (vitamins, amino acids, or other metabolites) for growth	penicillin technique or analogous procedures: cells grown in a medium lacking the accessory nutrients but containing penicillin or another agent that kills only growing cells. Auxotrophic mutants not able to grow in minimal medium survive.	if the cell suspension is spread on a complete medium containing the accessory nutrients and if the colony pattern is then replicated on a minimal medium, colonies that do not grow on the minimal medium are auxotrophs.
Mutants that lack the ability to utilize a special substrate	penicillin technique and/or direct isolation of pinpoint colonies: the cell suspension is spread on a nutrient agar that contains the substrate utilizable by the wild-type cells at normal concentrations (0.5 vol%), and the substrate accessible by the desired mutants at a very low concentration (0.005 vol%). Pinpoint colonies are transferred and screened.	comparison of colony patterns on agar plates containing different substrates; mutants unable to grow on a substrate will need a different nutrient for growth and are therefore recognized. Excretory mutants can be recognized by staining reactions (pH indicators) or by dyes added to the agar or after colony growth.
Temperaturesensitive (conditional lethal) mutants	penicillin technique to kill the wild-type cells growing at their upper temperature limit.	comparison of colony pattern on plates that have been incubated at different growth temperatures. Only those colonies that grow, e.g., at 25 °C but not at 37 °C are isolated.
Mutants derepressed or constitutive for catabolic enzymes	1) continuous culture with the substrate as growth-limiting factor; 2) alternating growth on two different substrates; 3) growth in the presence of an agent suppressing induction (antiinducer).	If the cell suspension is spread on a nutrient agar containing a noninducing substrate and after incubation the colonies are sprayed with a solution containing the constitutively utilizable substrate + indicator + inhibitor of enzyme protein synthesis, only constitutive mutants immediately degrade the substrate and change the indicator.
Mutants derepressed or constitutive for anabolic enzymes	growth in the presence of an antimetabolite that inhibits the growth of the wild-type cells. Among the resistant cells are some mutants that are not subject to end product repression.	only the resistant mutants grow, colonies of a clone forming the enzymes of a biosynthetic pathway constitutively will be surrounded by a halo of satellite colonies due to the excretion of a metabolite.

cell constituents have lower or higher densities than the average cell mass, the cells can be incubated under conditions that promote synthesis only in the parent or the mutant cells, followed by centrifugation in a sucrose gradient. Cells rich in lipids (poly(β-hydroxybutyric acid), triglycerides), glycogen, calcium dipicolinate, magnetosomes, etc. can thus be separated. In other cases tactic responses, such as migration in light–dark fields (phototaxis), in gradients of nutrient (chemotaxis), or oxygen concentrations (aerotaxis), can be used to select mutants that are defective in transport systems or in perception mechanisms. Adsorption on particle surfaces (glycogen or starch granules, lipid droplets, lignocellulose particles) followed by fractional centrifugation can be used to select for mutants that have altered surface structures. The separation efficacy can be increased by the use of column chromatography or by suicide techniques. *Suicide techniques* employ compounds that are converted by the wild types to toxic compounds; this lethal synthesis will finally kill the parent cells. Examples are monofluoroacetate, bromopyruvate, or chlorate, which are converted into fluorocitrate, bromolactate, or chlorine, respectively. The mutants are unable to catalyze such conversions and will therefore survive. With this methods it is possible to select for cells that are deficient in nitrate reductase (chlorate, perchlorate), or for fermentative mutants that have lost the ability to form acids (bromide, bromate). Successful biotechnology in many cases depends on the background information and the ingenuity of the researcher in selecting, recognizing, and manipulating the desired organism.

In most cases, a single random mutagenesis decreases the characteristic of an organism that is to be changed, such as, for instance, the catalytic performance of an enzyme. By applying *high-throughput screening* technologies, it

is, however, possible to screen large numbers of strains that are produced by random mutagenesis and find the valuable ones with beneficial mutations. Thus, by going through several rounds of random mutagenesis on the one hand and screening for the desired phenotype on the other, this process will identify those strains with considerably improved properties for production [87].

4.4.4. Targeted or Site-Directed Mutagenesis

Site-directed mutagenesis allows modifying a DNA sequence and thus the protein that is coded by this sequence in a specific and well-controlled way. Thus, it is possible to exchange one or more amino acid within the primary structure of the protein and thereby alter its functionality, for instance the catalytic performance of an enzyme. Compared to random mutagenesis, this is the more straightforward and direct approach not relying on chances that a genetic change may occur at a site that is useful for strain improvement. However, it requires detailed information on the three-dimensional shape of the protein and its primary structure. Many different approaches for targeted genetic alterations have been described that cannot be fully reviewed here. We will summarize the most widely applied and flexible concept of oligonucleotide-based mutagenesis.

In *oligonucleotide-based mutagenesis*, the gene of interest is cloned in a plasmid. After denaturation of the double-stranded circular DNA, oligonulceotides are added to the system that share sufficient sequence homology with the coding strand of the gene to allow for hybridization. However, at the site where the mutations should be introduced the sequence of the olignucleotide is altered. Since this is only a minor portion of the entire olignucleotide, hybridization still occurs but the base exchange has been introduced. Figure 16 sketches the underlying principle.

Chain extension by DNA polymerase and ligation results in a double-stranded DNA with one mutant strand and one wild-type strand. When these plasmids are then introduced in bacteria by transformation, semiconservative replication produces homoduplexes with both strands being either of the wild-type or the mutant. When colonies are grown, one can now screen for those strains in which the mutant plasmid has prevailed.

Many more experimental options exist to introduce site-specific mutations. Many of these are based on polymerase chain reaction (PCR) and the application of primers that already hold the mutation, or insertion or deletion. The interested reader is referred to Bowen [88].

The aim of modern metabolic engineering is to study the cell as an integrated system of genetic, protein, metabolite, and pathway events that are continually changing. This approach should help to optimize the production of substances or to produce substances with improved properties. Historically, metabolic engineering is the targeted recombination of the DNA for proteins involved in the metabolism or in regulation. Today, the objective of metabolic engineering is to quantify the pathway alterations in response to environmental mediators taking into account the entire metabolism. Knowledge of in vivo flux distributions in cells at different physiological states is of increasing importance for the evaluation of biotechnological processes. Gene expression data provide information on pathways relevant to the metabolic models. Furthermore, the so-called *combinatorial biosynthesis* uses techniques from molecular biology to alter or combine genes from biosynthesis pathways of the secondary metabolism to generate new products with improved pharmacological profil. The importance of studying the entire metabolism rather than one gene or protein at a time has become increasingly relevant with the advent of high-throughput genomic and proteomic technologies, especially microarrays. The DNA microarray technology will gain great importance in the field of future biological research developing into a key technology of the 21st century hence revolutionizing modern biotechnology. DNA chips are used as biosensors in industrial analysis, biomedical diagnosis, and forensic science. Although this technology provides a powerful tool that is widely utilized for gene expression, it is just beginning to find applications outside of genomics. Further development of protein, cell, and tissue chips will make it possible in the future to carry out miniaturized, highly parallel analysis of metabolic pathways. The challenge is to transfer these principles into technically applicable and precise ana-

Figure 16. Site-directed mutagenesis of cloned DNA by oligonucleotide mutagenesis

lytical systems that can be used for many applications repeatedly.

5. Cultivation and Bioprocesses

In this chapter, only the basic requirements for bioprocesses are described very shortly. For any further details concerning different types of bioprocesses, bioreactors, kinetics, sterility, and cleaning, the reader is referred to (→ Biochemical Engineering). Very detailed information about the monitoring and control of bioprocesses can be found in this contribution in Chapter 8.

Bioprocesses [89, 90] are used for the transformation of organic matter with the help of biocatalysts, such as living cells, dead cells, or their components, e.g., enzymes [91, 92]. Bioprocesses are utilized for chemical syntheses and for the conversion of waste material to either useful products (recycling) or effluents harmless to the environment (waste treatment). The outstanding feature of bioprocesses is their high synthetic potential to carry out a series of very complicated chemical reactions in a one-step process. Classic biocatalysts are yeasts, fungi, and bacteria; animal and plant cell cultures have become important only in more recent times (see Chapter 9). Process development [93] [94] [95] involves the areas of biology (strain development and bioregulation), reactor design, process control [96], and medium design [97, 98] as well as downstream processing (product recovery, see Chapter 7).

5.1. Isolation of Microorganisms

Microorganisms can be purchased from culture collections. But "microbes are everywhere, the environment selects," and a desired type of microorganism can often be isolated from its most probable natural habitat. For example, methanogenic bacteria are present in the anoxic mud sediments of ponds and lakes, hemoglobin-degrading bacteria in abattoirs, and hydrocarbon-oxidizing bacteria around oil fields or leaky engines of motor cars. From samples of these materials, bacteria can be isolated by enrichment culture. The technique of enrichment culture is simple and straightforward [99, 100].

By establishing defined environmental conditions with respect to the energy, carbon, and nitrogen sources; hydrogen acceptor; gas atmosphere; temperature; pH value; light; etc., and by inoculating with a mixed population that contains the desired metabolic type, the best adapted organism will dominate and overgrow all accompanying organisms.

Liquid enrichment culture is recommended if the fastest growing organism is desired. In this case, the organism is repeatedly transferred from the original liquid culture through several subcultures. If, however, a great number of strains with only slightly differing traits are to be separated, the *direct plating method* is the preferable technique: the inoculum is diluted and spread on a solidified enrichment medium (agar dish). During incubation the cells form colonies and can be isolated separately.

Whereas formerly these kinds of naturally pure or well-balanced mixed cultures were used in industrial practice (e.g., yeast fermentations, vinegar and cheese production) now only pure cultures are used. Pure cultures are obtained by diluting the enrichment culture and spreading the suspended cells on an agar surface or distributing the cells in an agar medium. After incubation, single colonies are isolated and streaked on various media to test for commensalic bacteria. Finally, a clone of the desired organism is obtained as a pure culture.

Preliminary results indicate that previously noncultivable microorganisms could be the key to the biosynthesis of active substances. The genes responsible for the expression of the natural substance biosynthesis could be inserted into microorganisms which can be grown easily, a procedure known as the *metagenome approach*. The metagenome is a set of all genetic material from organisms which cannot be cultured, e.g., from the soil or from communities of organisms. The development of the metagenome techniques becomes possible with the development of high-throughput techniques. The development of high-throughput DNA sequencing began in the early 1990s as simplifications and automation made it possible to decode the sequence of entire genomes. In 1995 the first full genome sequence was published, that of the Gram-negative bacterium *Haemophilus influenzae*. Of particular interest for biotechnology is the possibility of sequencing microbial production strains developed by repeated random mutagenesis and screening. A comparison with precursor strains could identify the mutations responsible for increased production. That way, production strains could be designed with just a minimal number of defined mutations [101].

Designer Bugs. The term used for microorganisms tailored by genetic engineering methods so that they can carry out desired biochemical conversions efficiently is designer bugs. Contrary to the strategy used in the past to obtain microorganisms for the production of a desired product by coincidental mutagenesis and selection, genetic engineering has opened up the possibility of customized construction of production strains by *metabolic engineering*. The genome permits insight into the entire metabolic potential of the organism. This insight is currently limited because the function of many gene products is not yet known. Organisms, such as *E. coli, Bacillus subtilis, Corynebacterium glutamicum, Pichia pastoris*, or *S. cerevisiae*, are preferentially applied in the development of designer bugs. Further important aspects governing the choice of host organism for a designer bug are knowledge of metabolism, regulation mechanisms, growth properties, and hazard potential. Based on methods developed in the last few years for the analysis of the genome, transcriptome, proteome and metabolome, which thus permitted a holistic consideration of the organism ("systems biology"), it will be possible in future to develop designer bugs for biotechnological production of a desired product considerably more quickly and specifically than in the past.

A list with mostly all culture collection worldwide can be found in the internet [102] under the URL http://www.bacterio.cict.fr/collections.html and in ref. [103 – 105].

5.2. Requirements for Growth

The process solution must primarily supply carbon and energy. In order to maintain growth, nutrients, trace elements, and such growth factors as vitamins must be added to the process solution. Appropriate selection of the medium components is essential for proper functioning and activity of the biocatalysts involved in the reaction.

Table 3. Standard nutrient media

a) *Minimal medium for bacteria*	
K_2HPO_4	0.5 g/L
NH_4Cl	1.0 g/L
$MgSO_4 \cdot 7\,H_2O$	0.2 g/L
$CaCl_2 \cdot 2\,H_2O$	0.1 g/L
$FeSO_4 \cdot 7\,H_2O$	0.01 g/L
Glucose	5.0 g/L
Trace element solution	1.0 g/L
b) *Complete medium for bacteria*	
Peptone	10 g/L
Yeast extract	1.0 g/L
NaCl	2.0 g/L
$MgSO_4 \cdot 7\,H_2O$	0.2 g/L
c) *Complete medium for fungi* (pH 6.0)	
Malt extract	10 g/L
Yeast extract	4 g/L
Glucose	2 g/L
KH_2PO_4	0.5 g/L
NH_4Cl	1.0 g/L
d) *Vitamin solution for soil and water bacteria*	
Biotin	0.2 mg
Nicotinic acid	2.0 mg
Thiamin	1.0 mg
Sodium 4-aminobenzoate	1.0 mg
Sodium pantothenate	0.5 mg
Pyridoxamine	5.0 mg
Cyanocobalamine	2.0 mg
Distilled water	100.0 mL
Two to three mL of this solution is added to 1 L of nutrient solution.	
e) *Trace element solution*	
$MnCl_2 \cdot 4\,H_2O$	3 mg/L
$CoCl_2 \cdot 6\,H_2O$	5 mg/L
$CuCl_2 \cdot 2\,H_2O$	1 mg/L
$NiCl_2 \cdot 6\,H_2O$	2 mg/L
$Na_2MoO_4 \cdot 2\,H_2O$	3 mg/L
$ZnSO_4 \cdot 7\,H_2O$	5 mg/L
H_3BO_3	2 mg/L

The growth of microorganisms is dependent on the presence of water or moisture. Nutrients to be used as sources of energy and for synthesis of cell constituents are dissolved in water. The growth requirements for various microorganisms are different, and many recipes for the composition of nutrient media are known. Basically, all chemical elements that constitute the cell substance have to be present in utilizable forms. There are ten *macroelements* that are constituents of all organisms: carbon, oxygen, hydrogen, nitrogen, sulfur, phosphorus, potassium, calcium, magnesium, and iron. In addition, there are *microelements* (trace elements), such as manganese, nickel, cobalt, molybdenum, zinc, copper, vanadium, boron, chlorine, sodium, selenium, silicon, tungsten, and a few others, that are not required by all organisms. The compositions of a few simple synthetic nutrient media are presented in Table 3.

5.2.1. Chemical Composition of Bacterial Cells

Bacterial cells harvested by centrifugation from a culture growing in liquid medium contain about 70 wt% water. The elemental assay of the dry mass of *E. coli* is: approximately 50 % carbon, 20 % oxygen, 14 % nitrogen, 8 % hydrogen, 3 % phosphorus, 1 % sulfur, 2 % potassium, 0.05 % each of calcium, magnesium, and chlorine, 0.2 % iron, and a total of 0.3 % trace elements. The organic analysis of the dry mass of cells is presented in Table 4. It should be noted that the values refer to a specific bacterium grown in a specific environment and harvested in a specific phase of growth. The results may differ if, e.g., the cells encountered limitation of the nitrogen source and accumulated poly(β-hydroxybutyric acid) (up to 90 wt%) or glycogen (about 50 %) within their cells.

Table 4. Overall macromolecular composition of *Escherichia coli* (mass percent, dry matter basis) [106]

Protein	55.0
RNA	20.5
DNA	3.1
Lipid	9.1
Lipopolysaccharide	3.4
Peptidoglycan	2.5
Glycogen	2.5
Total macromolecules	96.1
Soluble pool of building blocks, vitamins	2.9
Inorganic ions	1.0

5.2.2. Carbon and Energy Sources

Only autotrophic organisms are able to synthesize all organic cell constituents from carbon dioxide as the main carbon source. All others derive the cell carbon from organic compounds, which usually serve as both carbon and energy sources; they are partially assimilated and partially oxidized (dissimilated). Glucose, the monomeric constituent of polysaccharides such as cellulose or starch, can be used by the majority of microorganisms. Many other natural

compounds can be utilized and degraded by one or another microorganism.

5.2.3. Accessory Nutrients

In addition to carbon and energy sources, many organisms require accessory nutrients (growth factors), such as vitamins, amino acids, purines, or pyrimidines (see Table 3).

5.2.4. Sulfur and Nitrogen

These elements can be used in their oxidized forms as sulfate and nitrate. Ammonium ion is the most common nitrogen source for microorganisms.

5.2.5. Oxygen

The oxygen atoms of the cellular constituents are mainly derived from water, substrates, or carbon dioxide. Atmospheric oxygen serves mainly as a terminal hydrogen acceptor of aerobic respiration, being reduced to water.

5.2.6. Complex Media

Many microorganisms can grow in a simple nutrient medium such as that listed in Table 3 a. For *Leuconostoc mesenteroides* such a synthetic medium contains 40 components. If the nutrient requirements of an organism are not exactly known, complex nutrient media can be used, such as yeast extract, yeast autolysate, peptone (Table 3), meat extract, wort, carrot juice, coconut milk, or horse manure extract. In other cases complex media are used for economical reasons, for example, whey permeate, corn steep liquor, soybean extract, or molasses.

5.2.7. Solid Media

For solidification of media, agar is added at a concentration of 1.5 to 2.0 wt%. Agar melts at 100 °C and solidifies on cooling to below 45 °C.

5.2.8. Hydrogen Ion Concentration

The majority of microorganisms prefer a pH of about 7.0. However, there are acidophilic and alkaliphilic microorganisms. Yeasts and other fungi prefer pH 5.0. Buffers, in most cases phosphates, are used to maintain the desired pH, although the CO_2/HCO_3^- system or organic substances may do as well. The pH value is very important: the drop from pH 7.0 to pH 6.0 means a tenfold increase in the concentration of H^+ ions, which is a significant change.

5.2.9. Carbon Dioxide

Many microorganisms require a higher concentration of CO_2 than exists in the atmosphere, such as 10 vol%. This requirement applies to those bacteria that in their natural habitats (intestinal tract, tissue, milk, blood, fermenting juices) are exposed to high CO_2 partial pressures.

5.2.10. Aeration

All obligately aerobic microorganisms require oxygen as an electron acceptor for energy generation. For growth in thin layers on liquid or solid media atmospheric oxygen may suffice. In liquid media aerobic bacteria grow only on the surface if the medium is not agitated and aerated. Only dissolved oxygen is utilized; its solubility in water is very low (6.2 mL/L at atmospheric pressure and 20 °C). Therefore oxygen has to be supplied continuously to the cell suspension growing in submerged culture in flasks or fermenters. To meet the increasing oxygen demand in a growing culture, the speed of agitation, the oxygen concentration in the gas phase, and the total gas pressure can be increased. Various kinds of fermenters have been designed to increase the gas transfer from the gaseous to the liquid phase. The final cell density and yield of microorganisms depends on the rate of oxygen transfer. For fermenter design and scale-up, both the respiration rate (oxygen uptake) of the microorganisms and the oxygen transfer rate from gaseous to liquid phase have to be known. Because the formation of desired products is highly dependent on oxygen supply – whether the cells

are able to take up oxygen at their maximum respiration rate or only much less – aeration poses one of the most important problems in fermenter technology.

5.2.11. Anaerobic Techniques

For the growth of strictly anaerobic bacteria the complete exclusion of oxygen is required. Anaerobic techniques involve deaerated nutrient solutions, tightly sealed flasks, incubation in anaerobic jars, the use of chemical oxygen absorbers (pyrogallol, dithionite or the "gas pak," which contains hydrogen- and carbon dioxide-evolving agents and a catalyst to promote the oxyhydrogen reaction), resazurin as a redox indicator, anaerobic hoods, and skilled hands to practice these anaerobic techniques.

5.2.12. Media Preparation

Substrates for industrial applications are usually included in complex media, which must be supplemented with special compounds, such as a nitrogen source, various nutrient salts, or certain trace elements. Organic precursors are also added in some cases for efficient product formation. Many of the feedstocks need appropriate pretreatment in order to provide for good assimilation by the microorganisms. Starch-containing materials are prepared by milling or steam treatment for softening and swelling. For many processes, especially when yeasts are used, starch must first be broken down to sugar by treatment with amylase derived from barley malt or with microbial amylases. Other feedstocks, such as wood, must be pretreated with acid or alkali. Sulfite liquor is stripped from sulfur dioxide by aeration or neutralization. Molasses is purified by acidification and centrifugation or filtration. In some cases heavy metals have to be removed from feedstocks prior to their use. For processes using solid substrates, see [107].

In general, the raw materials are dissolved or suspended in water and the resulting medium is heated, filtered, and sterilized. The complex composition of the media used in industry causes considerable problems. For downstream processing (harvest, concentration, and purification of product) or for analytical assays during the process, additional pretreatment of the raw material is needed to avoid unfavorable side effects.

5.3. Sterilization

The basis of microbiological laboratory methods and of the conservation of food and feed products is the killing of microorganisms. Sterilization means the removal of living microorganisms, and can be achieved by moist heat, dry heat, filtration, irradiation, or chemical means [108].

5.3.1. Moist Heat

Vegetative cells of bacteria and fungi suspended in water are killed at temperatures around 60 to 80 °C within 5 to 10 min; yeast and fungal spores are killed above 80 °C, and endospores of bacteria at 120 °C within 15 min. Because endospores of bacteria are highly tolerant to various environmental conditions, they are ubiquitous and are distributed through the air. Their presence requires that all nutrient media and canned foods be sterilized in an autoclave at about 121 °C for 20 min. If conditions do not allow the germination of spores and the growth of spore-forming bacteria, e.g., in acid fruit juices, jam, or desserts, heating to 80–100 °C for 10 min will suffice. This is called partial sterilization or pasteurization.

5.3.2. Dry Heat

For killing bacterial endospores by dry heat, longer exposure times and higher temperatures are required than with moist heat. Glass and other heat-resistant equipment can be sterilized for 2 h at 160–180 °C in a dry oven. In any case appropriate indicators or soil samples that contain bacterial spores are included in the oven to test whether adequate temperatures have been reached and even the extremely heat-resistant spores have been inactivated.

5.3.3. Filtration

Solutions containing thermolabile compounds can be sterilized by filtration through nitrocellulose membranes, kieselguhr, porcelain, asbestos, and others. Usually filters with a pore size $<0{,}2$ µm are used.

5.3.4. Irradiation

UV irradiation is used to keep rooms partially sterile. Bacteria and their spores are killed rather quickly, but fungal spores are only moderately sensitive to radiation. Ionizing radiation (X-ray, gamma radiation) is used to sterilize food and other compact materials.

5.3.5. Chemical Means

Ethylene oxide is used to sterilize food, plastics, glassware, and other equipment. β-Propionolactone and diethyl carbonate are added to nutrient solutions. The presently used soaps and detergents applied at moderate temperature kill all vegetative cells and even many spores. Cleaning by the methods practiced in the kitchen provides almost sterile glassware.

Remarkably, the killing of microbes is a process that follows first-order reaction kinetics. In a population there are allways some cells or spores that are more resistant than the majority. Accordingly, sterilization procedures are most likely to be effective on relatively clean substrates.

5.4. Types of Bioprocesses

In chemical technology, a choice is to be made between batch processes or continuously operated processes. Many parameters usually favor the second over the first choice. However, in biotechnology, the batch process still predominates. This specific problem is treated in more detail (also in regard to engineering aspects) in → Biochemical Engineering.

5.4.1. Surface Culture

Surface cultures are mostly used when fungal mycelia act as catalysts. Mycelium is grown in shallow pans containing a small volume of the medium. As the mycelium grows, it eventually forms a compact mat. This method was typically used in the production of acids, such as citric acid. In large-scale production, surface culture is being abandoned more and more and replaced by the submerged culture method [109 – 111].

Surface cultivation is usually applied in the lab scale in fungal research. Large Erlenmeyer flasks or specially designed vessels, such as the Fernbach, Roux, or Sakaguchi flasks, containing small volumes of liquid are used. The flasks and liquid are sterilized and inoculated with spore suspensions or small pellets of mycelium. Growth and product formation are dependent upon the depth of the medium layer and the amount of surface provided by the flasks, which in turn affects the necessary oxygen supply.

In large-scale production large pans are used. They are filled with substrate, inoculated, and then kept at controlled temperature and air humidity. Pans are stacked on suitable racks, and connected with a system of overflowing tubes. The liquid medium is poured in at the top. In this way, an entire stack can be loaded at once. If the stack is designed appropriately, it can be sterilized, inoculated, aerated, and maintained under controlled conditions. The same principle can be applied for solid substrates, which are first inoculated and then loaded into the pans. The material is spread at a thickness of several centimeters onto screens or perforated metal sheets.

Columns filled with carrier material onto which the microbes are immobilized are also considered a surface culture as long as the column is not completely flooded. The medium is trickled through the column and air is injected at the bottom. The product is then collected from the carrier, which is made of wood shavings, plastics, or ceramics. This type of surface culture has been used for vinegar production and sewage treatment. However, it was abandoned and replaced with submerged culture. Remarkably, the immobilization methods that were developed for such biocatalysts as living cells, resting cells, enzymes, or organelles are formally similar to these conventional processes.

5.4.2. Submerged Culture

In this process, the microbes are suspended in the liquid medium. The simplest example of a submerged culture consists of a vessel without any agitation device, in which microorganisms settle at the bottom and form a compact layer. This is the classic arrangement for all types of ethanol-producing processes. Some agitation will occur,

however, from the movement of rising carbon dioxide bubbles.

For submerged, *anaerobic* processes, simple agitation devices for gentle mixing will suffice. This configuration allows for the mixing of liquid and gas. Carbon dioxide or other gases, such as nitrogen, can be added during the process.

5.5. Process Layout

5.5.1. Reactors

Appropriate reactors in biotechnology have to meet the requirements for agitation, aeration, corrosion resistance, and aseptic operation. Various designs of stirred vessel are therefore used in the laboratory and in production plants. Container construction is based on principles similar to reactors used in heterogeneous catalysis.

In former times, bioprocesses were carried out under nonsterile conditions and took place in vats of wood. Beer today is brewed in large cubical containers coated with ceramic tiles. For the more conventional surface processes (citric acid, acetic acid), small pans were used.

A basic problem in aerobic processes is the efficient transport of oxygen into the liquid and the microbial cells. Very efficient devices have been developed to provide air for aerobic reactions. Some examples of more modern reactor configurations for agitation and aeration are shown in Figures 20 and 21.

5.5.2. Containments for Anaerobic Processes

Large units for anaerobic processes are made of wood, metal, or coated concrete. They have no covers and consequently cannot be operated aseptically. However, submerged anaerobic processes can be performed under conditions that favor the formation of product and inhibit the accumulation of unwanted organisms by proper selection of reaction parameters, such as pH and temperature. Lactic acid, for example, is produced at 50 °C and low pH, and the development of competing microbes is negligible.

In other cases, closed vessels are used. They are usually made of stainless steel, have large capacities of up to 1000 m^3 or more, and are equipped with agitators and, if necessary, with cooling and heating coils. Gases that form during the process (CO_2, H_2, or evaporated solvents) are collected at the top. These large tanks have openings for loading, inoculation, harvesting, and cleaning. Large units are mostly sterilized with steam.

Extremely large containments with capacities of thousands of cubic meters are used in sewage treatment. They are usually constructed of concrete and allow automatic feed and removal of material. Sludge treatment plants are often equipped with heating elements to allow thermophilic processes for methane production. The gas is collected and stripped of hydrogen sulfide if necessary.

5.5.3. Reactors for Aerobic Processes

Bioreactors used for aerobic processes are basically similar to those used for anaerobic processes. In addition, they contain devices for aeration and agitation. The capacities used in industry may vary considerably, from 10 to 200 m^3. Large tanks of 1000 m^3 and more are also used for aerated, sterile processes (e. g., glutamic acid). For aseptic processes the tank is sterilized with steam before loading; a slight overpressure is often maintained during cultivation. Agitation principles vary considerably and include mechanical as well as pneumatic and hydrodynamic systems.

The most commonly used type of bioreactor is the *stirred tank reactor* (STR) using a flat blade turbine (FBT) for agitation (Fig. 17). This configuration provides excellent mixing and mass transfer in media of low viscosity. Drawbacks are high power demand, poor performance with highly viscous liquids, and rather poor interchange of material between mixing regions around the blades. Air is normally injected by a sparger. Larger units are equipped for pneumatic agitation, in which movement is caused by injected air. For proper hydrodynamic control, various kinds of baffles and draft tubes can be inserted.

5.5.4. Inoculation

After inoculation with the microorganisms, the process should start immediately and the reaction should proceed fast. The amount of active

cell culture added is therefore critical and depends on the size of the batch. Scaling-up from the original starter culture to the inoculation broth is done in several steps in large-scale industrial processes (Fig. 19). The starter culture is kept deep frozen (−80 to −90 °C) in sealed vials or in vials that were previously subjected to lyophilization (a). They can be stored in this way for several months or even years without any damage. For short-term storage at 4 °C, agar slants are prepared (g) and purity is tested on Petri dishes (h) before inocula are scaled up for production.

Figure 17. Stirred tank reactor (STR) equipped with flat blade turbine (FBT) and baffles for agitation and a sparger for gas distribution
The ratio of H: D is usually 3 (max. 5).

For scaling-up, the liquid cell culture is placed in liquid broth, first in test tubes (b), then in small (c), and subsequently in large Erlenmeyer flasks (d) containing approximately 200 mL of medium. Proliferation of the culture takes place by shaking the flasks overnight at constant temperature. Larger amounts of inocula are then prepared in agitated and aerated fermenters of various sizes depending on the volume of the production plant (e, f). In the early stages of this procedure (steps a through d) the inoculum is transferred under sterile conditions in glove boxes.

In *fungal inocula* proper wetting of the spores is achieved by adding small amounts of surfactants to the broth. If inoculation by spare suspensions is not optimal, mycelial pellets can be used for start-up. *Bacterial spores* must be activated by thermal treatment before they can be used for inoculation. During the exponential growth phase of the bioprocess cells can be harvested for following inoculations.

5.5.5. Operation Modes

Optimum production depends strongly on process layout. The standard process is still the *batch operation*, which consists of loading, inoculation, processing, harvest, and cleanup of the vessel. The advantages of this procedure are its adaptability to weekly work hours and small losses in case of contamination or decreases in productivity.

Greater specific production can be attained by using *semicontinuous* or *sequential-batch* operations. In this method only a partial stream of the broth is withdrawn after completion of the reaction (e.g., 90 %) and new medium is added directly into the remaining volume. This type of operation is also called cyclic continuous production. Modern vinegar production is operated in the cyclic manner and maintained by fully automated process control.

Fully *continuous operation*, that is, the constant flow of medium into a reaction vessel and the simultaneous removal of an identical amount of the process solution, has shown the highest production rate. However, practical and biological constraints, especially the high contamination risk, have so far prevented the general introduction of continuous processing into biotech-

nology. Therefore, only processes that need not be carried out under aseptic conditions are operated continuously such as sewage treatment, methane formation, and feed yeast or ethanol production from sulfite liquor.

The potential advantages of continuous cultivation are substantial because of the efficiency of the process and the uniformity of the final product. As a result, much effort is being made to develop a sound basis of knowledge necessary for using this process strategy.

In contrast to large-scale industrial processes continuous cultivation methods are widely used in the laboratory [113 – 115]. The growth-controlling factor is either the concentration of nutrients in the medium (chemostat system) or the concentration of insoluble biomass sensed by optical measurement (turbidostat methods). The purpose of these control systems is to maintain a constant concentration of nutrients, cells, and metabolic products in the vessel (steady state). The kinetics of growth or product formation can

Figure 19. Preparation of inocula.
The individual steps a through h are explained in the text

be kept under precise control by selecting the appropriate dilution rate. All types of variations of the single-stage continuous cultivation are possible, such as multistage arrangements, with or without recycling.

5.6. Process and Product Overview

The potential of biotechnology consists in its ability to replace classical chemical production processes and to facilitate the production of new products. It is undisputed that, particularly in the area of basic and fine chemicals production, the use of biotechnological processes is meaningful since

- biotechnological processes are usually distinguished by their high specificity (relating to the conversion of substrates) and selectivity (relating to the product spectrum)
- biotechnological processes often use renewable resources as raw materials, thus contributing to the much discussed sustainability of products and processes
- biotechnological processes can be carried out under mild reaction conditions in terms of pressure, temperature, and pH.

In view of these facts, in the past hundred years a multitude of industrial biotechnological processes have been developed [116 – 120] whose efficiency exceeds that of chemical processes, and this has helped to establish them in the long run (Table 5 and 6). One interesting area is the production of fine chemicals. The term "fine chemicals products" refers to substances that are highly functional and for which world demand is typically quantities of less than 10 000 t/a. From a chemical point of view these products are usually distinguished by having several reaction centers and frequently by chirality. Classical syntheses of these substances include several reaction steps using stoichiometric quantities of reagents and often deploy extravagant protective group chemistry, expensive noble metal/heavy metal catalysts, and drastic reaction conditions, e.g., aggressive solvents. Here biocatalysis allows synthesis under considerably milder reaction conditions in terms of pressure, temperature, and acidity. At present, due to the excellent enantioselectivity of enzymes, white biotechnology methods are primarily used for the production of chiral compounds. Straathof et al. [121] list 134 industrial biotransformations. Just short of 90 % of the products described are chiral fine chemicals. In future, this field will undoubtedly acquire greater importance and new reaction sequences for the production of compounds with several stereo centres will be established.

Also bulk chemicals are produced by fermentation or biotransformation processes. Bulk products mean products exceeding 10 000 t annually. It is expected that, by the year 2010, 6–12 % of bulk products and polymers produced by chemical means will already be produced by biotechnological processes. High-volume, biotechnologically produced goods are to be found in the food, livestock feed, and the drinks and tobacco industries. A prime example of a bulk product derived by an enzymatic process is acrylamide. Global biotechnological production capacities have continually expanded in the last few years and are today probably in the region of 100 000 t/a. Monomers and polymers produced by biotechnological processes for the plastics and polymer industry are becoming increasingly interesting. Biotechnologically produced polymers, such as polylactide (PLA), 1,3-propandiol (PDO) and poly-3-hydroxybutyrate-co-3-hydroxyhexanoate (PHBH) could provide the basis for innovations.

As for the energy industry, besides bioethanol two further products should be mentioned: biogas and hydrogen. Whereas the technology for biogas recovery is state-of-the-art, hydrogen production is far more complex and requires long-term research efforts. Biogas recovery is a recycling method for residues. The product can be separated comparatively easily, which is crucial to the cost-effectiveness of the process.

6. Biocatalysis and Biotransformation

6.1. Introduction

Biocatalysis (also called biotransformation) is the conversion of one substance (substrate) to another (product) by a microorganism or an isolated enzyme. It is a chemical reaction catalyzed by a particular cellular enzyme or by an enzyme originally produced within the cell. Most

of these enzymes are necessary for the normal metabolism and reproduction of the cell. In biocatalysis, however, these enzymes are simply used as catalysts for chemical reactions. In addition to their natural substrates, many enzymes can utilize other structurally related compounds as substrates and therefore may catalyze nonnatural reactions upon addition of foreign substrates to the reaction medium. Thus, biocatalysis or biotransformation is a specific category of chemical synthesis.

6.2. Classification of Biocatalysts

Enzymes and whole cells can be applied in a biotransformation in many different forms. Usually a whole cell biotransformation is a growth decoupled process, so resting cells (harvested and washed after fermentation) are employed. The cells may be intact or permeabilized (e.g., for better substrate uptake). The different types of biocatalysts are:

- Whole or treated cells (e.g., lyophilized, permeabilized)
- Organelles
- Cell-free multienzyme systems
- Combination of individual cell-free enzymes
- Single cell-free enzyme

Isolated Enzymes may also be applied in different forms. In most cases, it is not necessary to purify an enzyme to homogeneity, a crude cell extract or partially purified solution may also be employed as biocatalyst. In some well-known technical enzyme preparations, several isoenzymes are present (e.g., pig liver esterase). In both whole cells and enzymatic biotransformations the catalytically active species is the enzyme. Enzymes can be subdivided into six classes (classified by the Committee on Enzyme Nomenclature of the International Union of Biochemistry) depending on the type of reaction they catalyze (Table 7) and are listed numerically in a catalogue published by the committee [125] (→ Enzymes).

6.3. History

Biocatalysis includes some of the oldest human known chemical transformations such as the use of yeast for baking or brewing or the use of chymosin from the stomach of young cattle for cheese production. Records proving these ancient technologies date back to about 7000 to 6000 BC.

Another old and well-known example is vinegar production, which has been known since the dawn of recorded history. It is the oldest example of microbial oxidation (Fig. 20).

The process has evolved along traditional lines of fermentation without knowledge of the underlying biochemistry. In 1862, PASTEUR described the biochemical nature of vinegar production [126]. Subsequently BROWN confirmed in 1886 that the oxidation of alcohol to acetic acid proceeded through acetaldehyde [127]. *Bacterium xylinum*, which causes the reaction to proceed, was first described by BROWN and is the first microbial catalyst.

Today, the oxidation of ethanol to acetic acid by acetic acid bacteria is well understood; it proceeds via two successive dehydrogenations,

which depend on the cytochrome system for electron transfer to atmospheric oxygen, the ultimate hydrogen acceptor:

Table 7. Classification of enzymes and their reactions

Class	Reaction
Oxidoreductases:	Enzymes catalyzing oxidation–reduction reactions involving oxygenation, such as C–H → C–OH, or overall removal or addition of hydrogen atom equivalents, for example CH(OH) → C=O and CH–CH→C=C. Dehydrogenases, oxidases, peroxidases, hydroxylases, and oxygenases are involved in this class.
Transferases:	Enzymes catalyzing the transfer of various groups (e.g., aldehyde, ketone, acyl, sugar, phosphoryl) from one molecule to another.
Hydrolases:	Enzymes catalyzing hydrolytic cleavage of C–O, C–N, C–C, etc. Esterases, amidases, peptidases, phosphatases, glycosidases, etc. are involved.
Lyases:	Enzymes catalyzing cleavage of C–C, C–O, C–N and other bonds by elimination, leaving double bonds, or by adding groups to double bonds.
Isomerases:	Enzymes catalyzing a change in the configuration of a molecule. Racemases and isomerases are involved.
Ligases:	Enzymes catalyzing the joining of two molecules with the accompanying hydrolysis of a high-energy bond. Such enzymes are often termed synthetases.

Figure 20. Biotransformation of ethanol to acetic acid

$$C_2H_5OH + \frac{1}{2}O_2 \rightarrow CH_3CHO + H_2O$$

$$CH_3CHO + \frac{1}{2}O_2 \rightarrow CH_3COOH$$

Other historical examples of biocatalytic oxidation are the oxidation of glucose to gluconic acid by *Acetobacter aceti* [128] and the oxidation of sorbitol to sorbose by *Acetobacter* species [129]. A variety of such early reports on biocatalytic conversions was collected by PLIMMER [130]. Since then many other books have been published on this topic.

In 1921, a microbial reaction for the stereospecific production of D-(−)ephedrine was described [131]. A yeast strain, cultivated to produce acetaldehyde from glucose, was found to condense benzaldehyde with acetaldehyde to form optically active L-phenyl-1-hydroxy-2-propanone. This product was in turn converted chemically into D-(−)ephedrine (Fig. 21). This is an example of a successful combination of chemical and biological reactions.

Figure 21. Chemoenzymatic synthesis of optically active l-phenyl-1-hydroxy-2-propanone and chemical conversion into D-(-)ephedrine

Biocatalyis reached its present significance much later, when specific modifications of steroids (or sterols) by microorganisms were discovered. Various steroid reactions, such as hydroxylation, epoxidation, dehydrogenation, isomerization, and hydrolysis, are performed by a wide variety of microbial enzymes. These include the following important reactions: reduction of androstenedione to testosterone by yeasts [132], hydroxylation of progesterone to 11-α-hydroxyprogesterone by *Rhizopus arrhizus* [133], 11-β-hydroxylation of C_{21}-steroids by *Curvelaria lunata* [134], introduction of a Δ^1-double bond into hydrocortisone by *Corynebacterium simplex* [135], 16-α-hydroxylation of 9α-fluorohydrocortisone by *Streptomyces reseochromogenes* [136], and elimination of the side chain of cholesterol by *Arthrobacter simplex* [137]. Many novel intermediates for the chemical synthesis of new steroids became available in this way.

In addition to the considerable practical value, the amazing versatility of microorganisms in the transformation of steroids provided an important theoretical background for the application of microbial enzymes to chemical synthesis.

Many of these reactions cannot be achieved by conventional chemical synthesis.

Table 8. Advances in biocatalysis

Biocatalytic synthesis	Example reactions
Transformation of steroids and sterols	hydroxylation (oxygenase), dehydrogenation (dehydrogenase), side-chain degradation (oxygenase), etc.
Transformation of terpenoids	hydroxylation of beta-ionone with monooxygenase from *Bacillus negaterium* [138].
Transformation of alkaloids	oxidation of morphine to 2,2′-bimorphin (pseudomorphine) by *Cylindrocarpon didymium* [139]; *N*-demethylation of codein to norcodein by *Mucus piriformis* [140].
Synthesis of semisynthetic antibiotics	synthesis of semisynthetic penicillins and cephalosporins (amidase).
Synthesis of organic acids	hydration of fumaric acid (fumarase), diterminal oxidation of alkanes (oxygenase), asymmetric hydrolysis of epoxysuccinic acid (hydrolase), etc.
Transformation of sugars	isomerization of glucose (glucose isomerase).
Protein synthesis	synthesis of plastein (protease), semisynthesis of human insulin (protease), etc.
Synthesis of nucleic acid related compounds	trans-*N*-ribosylation and trans-*N*-arabinosylation (phosphorylase), phosphorylation of nucleosides (phosphotransferase), pyrophosphorylation of nucleotides (pyrophosphotransferase), synthesis of sugar nucleotides (pyrophosphorylase), synthesis of coenzymes, etc.
Synthesis of amino acids	asymmetric hydrolysis of α-amino-ε-caprolactam, 2-amino-Δ^2-thiazoline-4-carboxylic acid, and 5-substituted hydantoins (hydrolase), amination of fumaric acid (aspartase), synthesis of L-tyrosine-related amino acids (β-tyrosinase), L-tryptophan-related amino acids (tryptophanase), etc.
Synthesis of amines	decarboxylation of amino acids (decarboxylase).
Synthesis of industrial chemicals	synthesis of alkene oxides (oxygenase), chiral alcohols and ketones (dehydrogenase), pyrogallol (decarboxylase), amides (nitrile hydratase), etc.

Innumerable biocatalytic conversions involving different types of reactions with organic compounds and natural products were found during the following years; some of them are very useful for chemical synthesis. Advances in biocatalysis are summarized in Table 8. Although biocatalysis has become an important technology for synthetic chemistry, it also has a high potential for many fields of biotechnology.

6.4. Characteristics of Enzyme Reactions Used in Biotransformations

Chemical reactions performed by biocatalysts (biotransformations) are essentially the same as those carried out in inorganic or organic chemistry.

Enzymes (or biocatalysts) used for microbial conversions increase the reaction rate by lowering the activation energy as normal catalysts do. The most striking difference between enzymes and chemical catalysts, however, lies in their substrate specificity. They catalyze specific reactions involving one or only a few structurally related compounds and they distinguish almost absolutely between stereoisomers or regioisomers. Therefore, only a very specific change in a functional group or bond of a compound is accelerated by the enzyme. As a result, one single product is expected as long as only one enzyme is involved in a conversion.

In contrast to chemical reactions that often require high activation energies (high temperature, pressure, etc.) biotransformations can be performed under considerable mild reaction conditions (Table 9). Due to the low energy input needed for biocatalytic processes and the high *atom utilization* (percentage of M_r of desired product to sum of M_r of all substrates), biotransformations are considered as an environmentally friendly alternative to classical organic chemistry processes. To compare biocatalytic and chemical processes on the basis of the amount of waste, Roger A. Sheldon [141] devised the "environmental quotient" (EQ), which is the quotient of the amount of waste product per kilogram of product (E) and an "unfriendliness quotient" (Q): $EQ = E \times Q$.

High catalytic efficacy is another characteristic property of enzymes. They increase the turnover rate without large energy requirements and only a small amount of enzyme is needed to catalyze the conversion of a large amount of substrate.

Table 9. General characteristics of enzymatic and chemical reactions

Parameter	Enzymatic reaction	Chemical reaction
Reaction conditions:		
Temperature	physiological	high
Pressure	atmospheric	high
pH	neutral	different
Reaction energy	enzyme conformation (van der Waals, hydrogen bonds, etc.)	thermal
Solvent	water, (organic solvents and ionic liquids under special conditions possible, e.g., low wateractivity)	water, organic solvents
Specificities (substrate, stereo-, regiospecifity)	high	low
Concentration of substrate and/or product	low	high

Table 10. Characteristics of biotransformation microbial conversion and fermentative production

Parameter	Biotransformation	Fermentative production
Microorganism	resting or treated cells	growing cells
Reaction	simple catalytic reaction (one or few steps)	life process (multistep reaction)
Reaction time	short	long
Starting materials	expensive substrates	cheap carbon and nitrogen sources
Product	natural and/or unnatural	natural
Product concentration	high	low
Product isolation	easy	tedious

As a result, enzymes exhibit their activity under mild reaction conditions, such as atmospheric pressure, temperatures around 20–40°C, and pH values near neutrality, where normal chemical catalysts are inactive. On the other hand, enzymes cannot function under drastic reaction conditions because of their delicate protein structures. The unique properties of enzymes are extremely useful when unstable molecules are to be converted without undesired side reactions.

There are two ways for using biocatalysts in the production of useful compounds: biotransformation and fermentation. *Fermentation* has been used since ancient times (e.g., alcoholic fermentation) and is still of industrial importance in the production of such compounds as organic acids, solvents, or antibiotics. In contrast to biotransformation, fermentation is considered to be a biologic method, because it results from the actual life process of the microorganisms. In other words, the reaction product results from the complex metabolism of the microorganism from cheap carbon and nitrogen sources. Therefore, living cells are required for fermentation, whereas this is not so important in biotransformation. Fermentation products are always natural products. Advantages and disadvantages of these two microbial processes are briefly summarized in Table 10. However, it is not always possible to draw a clear line between the two categories.

6.5. Types of Biocatalysts and Reaction Systems

Because biotransformations are essentially catalytic chemical reactions, a suitable catalyst for the desired conversion must be prepared carefully. Although conventional vegetative cell cultures are most commonly used, there are several alternative methods; some of these have already been operated commercially. These alternatives have been evaluated extensively with regard to, for example, increased yield, control of side reactions, simplified processes, and improved economy. They have great future potential.

Various types of biocatalysts are useful for microbial conversions (see Section 6.2. Any combination of these systems may also be possible. Several successful conversions are known in which multistep reactions are catalyzed by different catalysts (see Section 6.5.6).

6.5.1. Biotransformation with Growing Cultures

The substrate is added to the growth medium during inoculation or an appropriate phase of growth. The preparation and inoculation of the medium, addition of substrate, and incubation are successively carried out in one flask until the reaction is completed. Because of its extreme simplicity, this procedure is frequently used not only for screening (see Section 6.6), but also in large-scale production. Usually, the substrate is added directly to the medium without sterilization if the fully grown culture is the catalyst. Continuous chemostat methods may be used to maintain a steady state of growth, enzyme levels,

and substrate concentration. If high cell densities are required by the conversion or if the nature of the growth medium causes problems for the isolation of the product, the reaction should be performed after separating the cells from the medium, see next section.

6.5.2. Biotransformation Conversion with Previously Grown Cells

The microorganism is grown under suitable conditions and the cells are then collected by centrifugation or filtration. In this way, the cells retain most of their enzyme activity. For the conversion they are resuspended either in an incomplete medium (e.g., one without a nitrogen source; this prolongs cell viability and activity as well as possible cofactor regeneration) or in a simple reaction medium (e.g., a buffer solution or water containing the substrate). The reaction is then carried out directly or after suitable treatment of the cells. It is theoretically not important whether the cells are dead or alive. Vegetative, washed, and dried cells fall into this category. The advantages of this method are listed below:

1) Growth and conversion steps are controlled independently for optimization.
2) The grown cells can be stored for some period of time until initiation of the reaction.
3) The cell density for the conversion is easily controlled.
4) The reaction can be carried out under nonsterile conditions.
5) Product isolation is usually easier because of the simple composition of the reaction medium.

In some cases, however, the strict separation of microbial growth and conversion is considered to be unfavorable for economic reasons.

Depending on the ability of substrate permeability through the cell membrane these biocatalysts may have to be treated differently prior to their use.

6.5.2.1. Vegetative or Washed Cells

In cases where the cell membrane is permeable to substrate and product, no special technique is needed for the preparation of the cells and they can be used as vegetative or washed cells.

6.5.2.2. Permeabilized Cells

In cases where substrate or product molecules do not readily permeate the cell membrane, a modification of the cell becomes necessary. Commonly used techniques to change the permeability of the cell membrane to control the diffusion of substrate into the cell and of product out of the cell are: using surfactants, organic solvents, antibiotics or enzymes. Besides these chemical methods physical procedures, such as osmotic shock or freezing and thawing may also be useful [142]. The production of high-energy phosphate esters, such as adenosine 5-triphosphate, nicotinamide adenine dinucleotide, flavin adenine dinucleotide, or coenzyme A, is a typical example [143].

6.5.2.3. Dried Cells

Dried cells are an alternative to permeabilized cells. Drying causes structural changes in the cell wall or membrane. Contact between the cell enzyme and the substrate is more readily achieved. In some cases, drying also eliminates undesired side reactions, because some enzymes are damaged through drying. Dried cells are usually prepared by air-drying, lyophilization and acetone treatment. The powdered dried cells can retain their enzyme activities in the frozen state for years. They can be used as "instant catalysts" in the same way as normal chemical catalysts.

6.5.3. Biotransformation with Spores

Many fungal spores have as many useful enzymes as vegetative or grown cells. The fungi are cultivated under conditions that induce high spore yields. The spores are then separated from the mycelium and used as catalysts in a similar way as mentioned in the previous section. Processes using spores have the same advantages as those using grown cells. Spores are usually more stable than cells. Some types of spores can be stored for several years without loss of conversion activity. They usually do not germinate during the reaction, but in some cases germination is required for maximum conversion activity. The 11-α-hydroxylation of progesterone by

Aspergillus ochraceus spores represents a successful spore process [144]. Many other applications have been reported, e.g., fatty acids conversions, triglycerides, carbohydrates, or penicillin V [145].

6.5.4. Biotransformation with Immobilized Cells

Immobilized cells are cells that have either been fixed or bound to a surface, entrapped in a gel matrix, or retained in a membrane reactor. All of the above-mentioned cells can be immobilized. Numerous immobilization methods have been reported; they can be divided into the following four groups:

1) Entrapment or encapsulation in a porous polymer network, e.g., polyacrylamide, alginate, κ-carrageenan, gelatine, agar, collagen, cellulose, polyurethane, poly(vinyl alcohol).
2) Covalent, ionic, or physical attachment to an appropriate water-insoluble solid support, e.g., ion-exchange resins, silica gels, metal oxides.
3) Aggregation of cells by physical or chemical cross-linking with glutaraldehyde, polyethyleneimine, or other agents.
4) Retention of cells by membranes (microfiltration, cutoff 0.2–2 µm), e.g., in form of membrane reactors or hollow fiber modules [153].

In successful cases, the immobilized cells retain their activities over several months and show a higher operational stability than unsupported cells. Additional advantages are: 1) easy removal of the cells from the reaction mixture, 2) repeated use of the cells, 3) continuous operation of the reaction, 4) cell regeneration by immersion into an appropriate nutrient medium, and 5) easy product isolation. Some of these features are especially advantageous if the collection of a sufficient cell mass for the conversion is costly.

However, disadvantages must also be considered: 1) The catalytic activity of cells usually decreases during the immobilization procedure because the cells are partly damaged and permeability is further inhibited. This decreased activity can be compensated by increasing the cell density. 2) The immobilization itself sometimes requires special equipment. The conversion step, especially when operated continuously, also requires a special engineering design compared to conventional conversion processes. Examples of successful large-scale applications are listed in Table 11.

An advance in this field was the introduction of an immobilized system of growing cells

Table 11. A selection of commercial applications of immobilized biocatalysts: microbial cells or enzymes

Microorganism or immobilized enzyme	Methods of immobilization	Applications	Year of introduction	Ref.
L-Amino acylase from *Aspergillus oryzae*	adsorption to DEAE-Sephadex	optical resolution of racemic amino acids	1969	[146]
Escherichia coli (aspartase)	entrapment in χ-carrageenan gel	continuous production of L-aspartic acid from ammonium fumarate	1973	[147]
Brevibacterium ammoniagenes (fumarase)	entrapment in χ-carrageenan gel	continuous production of L-malic acid from fumaric acid	1974	[148]
Escherichia coli (aspartase) and *Pseudomonas dacunhae* (aspartate -decarboxylase)	entrapment in χ-carrageenan gel	continuous production of L-alanine from ammonium fumarate	1982	[149]
Penicillin acylase from *Escherichia coli*	entrapment in a cellulose triacetate matrix	production of 6-amino-penicillanic acid from penicillin G	1973	[150]
Glucose isomerase from *Bacillus coagulans* or *Streptomyces* species	many methods available	production of high-fructose syrup from glucose	1973	[151]
β-Galactosidase from *Lactobacillus bulgaricus, Aspergillus oryzae*, etc.	many methods available	production of low-lactose milk and production of sweetenings	1977	[152]
Whole cells *Arthrobacter sp.* (oxygenase)	retention by microfiltration in cross-flow membrane reactor	production of muconic acid (raw material for new resins, pharmaceuticals and agrochemicals)		[153]

into a conversion process. For example, cells entrapped in -carrageenan are viable and reproduce without loss of activity per unit cells [154]. The continuous production of ethanol from glucose by *S. cerevisiae* in κ-carrageenan [155] and the Δ^1-dehydrogenation of cortisol by *Arthrobacter simplex* in calcium alginate [156] are examples of such successful operations. Further improvement of this technique is now expanding into the application to complex multistep reactions, such as the production of antibiotics.

6.5.5. Biotransformation with Cell-free Enzymes or Purified Enzymes

In general, the use of cell-free enzymes or purified enzymes for conversions is expensive, because purification of enzymes is often tedious and time-consuming. Therefore, they are not so suitable for large-scale industrial production. However, there are several cases in which they are advantageous over systems using cells. Such cases are:

1) Poor substrate or product permeability through the cell wall
2) Problems caused by undesired side reactions
3) Commercial availability of the desired enzyme at an acceptable price

If an extracellular enzyme is used, cells are not involved at all.

Cell-free enzymes can also be used as immobilized catalysts [157]. The same techniques as those used for cell immobilization are available. Immobilization of penicillin acylase [150], L-amino acid acylase [146], lactase [152], and glucose isomerase [151] have been applied to commercial production. The entrapment of soluble enzymes in a membrane-type reactor with simultaneous coenzyme regeneration is an alternative to the use of cell-free enzymes. L-Amino acid dehydrogenases in combination with formate dehydrogenase as a coenzyme regenerator and nicotinamide adenine dinucleotide covalently bound to polyethylene glycol in a membrane reactor have been successfully applied to the continuous amination of keto acids yielding optically active amino acids [158]. L-Leucine is already produced commercially by this process.

Whitesides [159] has reviewed the potential applications of cell-free enzymes in organic synthesis.

6.5.6. Multistep Reactions Using Different Biocatalysts

In order to perform more than two sequential reactions, two or more different biocatalysts are sometimes required either simultaneously or sequentially. Theoretically, any combination of catalysts can be used for such multistep reactions. Examples of successful applications are: continuous production of L-alanine from ammonium fumarate via L-aspartate as the intermediate by immobilized *Escherichia coli* (aspartase) and *Pseudomonas dacunhae* (L-aspartate β-decarboxylase) cells [149], complete condensation of racemic homocysteine by washed or dried *Pseudomonas putida* (racemase) and *Alcaligenes faecalis* (*S*-adenosylhomocysteine hydrolase) cells [160], complete hydrolysis of racemic α-amino-ε-caprolactam (see Section 6.6.2.1), and continuous amination of α-keto acids to L-amino acids by two types of cell-free enzymes (see Section 6.5.5).

Another remarkable example is the synthesis of coenzyme A from pantothenic acid, L-cysteine, and ATP (or AMP), which proceeds through five sequential steps (see below) and is commercially performed solely with *Brevibacterium ammoniagenes* cells [161, 162].

Step 1:	pantothenic acid + ATP $\rightarrow$ phosphopantothenic acid + ADP
Step 2:	phosphopantothenic acid + L-cysteine + ATP $\rightarrow$ phosphopantothenoyl-L-cysteine + ADP + inorganic phosphate
Step 3:	phosphopantothenoyl-L-cysteine $\rightarrow$ phosphopantetheine + CO_2
Step 4:	phosphopantetheine + ATP $\rightarrow$ dephosphocoenzyme A + inorganic pyrophosphate
Step 5:	dephosphocoenzyme A + ATP $\rightarrow$ coenzyme A + ADP

6.5.7. Multiphase Reaction Systems

Since their discovery, enzymes have been thought to be inert catalysts in organic solvents. This is basically true, but enzymes have become available that are catalytically active in water-miscible organic solvents. Many reactions that are impossible in water because of kinetic or thermodynamic reasons can be performed in organic solvents [163, 164] (e.g., transesterification reactions [165]). Chemically modified peroxidase exhibits 21 % of its activity in benzene

as compared to that of the unmodified enzyme in aqueous solution [166]. Polyphenol oxidase converts nearly 100 % of phenol to catechol when the reaction is carried out in chloroform containing only 1–2 % water [167]. Such liquid–liquid two-phase systems with low water content can also be used to shift the hydrolytic equilibrium toward water elimination. The synthesis of esters, amides, and peptides by this method shows great practical potential.

Multiphasic conversion systems using microbial cells as catalysts have also been extensively studied, especially in the case of lipophilic compounds, which have a limited solubility in water. In some cases, increased reaction rates and/or product yields have been achieved.

6.6. Process Design

6.6.1. General Considerations

When designing a biocatalytic process many important aspects require careful consideration. Besides the essential question of the type of enzyme used for biocatalysis there is the selection of a compound to be synthesized and a survey on available substrates and routes or reactions that are of special importance in designing a conversion process (also see Chapter 5).

6.6.1.1. Evaluating Enzyme Potential

When a new conversion or a new enzyme useful to biocatalytic conversions is discovered, the question as to the potential of the new enzyme for practical purposes must be answered first. An example for a high-potential biocatalysis with practical application in the pharmaceutical industry is L-phenylalanine dehydrogenase (PheDH, EC 1.4.1.20) from *Thermoactinomyces intermedius* for the conversion of ketoacid acetals to acetal amino acids [168] (Fig. 22). The amino acid acetal is a precursor for Omapatrilat®, an antihypertensive drug, which inhibits the angiotensin-converting enzyme (ACE) and neutral endopeptidase (NEP). The synthesis is carried out in 16,000 L batch reactions with heat dried *E.coli* cells containing the cloned and overexpressed PheDH from *Thermoactinomyces intermedius* and the formate dehydrogenase from *C. boidinii* for cofactor regeneration. Yield (97 %), conversion (97 %), and optical purity of the product (ee > 99 %) are very high.

Figure 22. Synthesis of acetal amino acid (Bristol-Myers Squibb)

Another interesting example is the production of L-tyrosine and L-dopa (dihydroxyphenylalanine) by bacterial β-tyrosinase [169]. This enzyme has long been known to catalyze the α, β-elimination of L-tyrosine to phenol, pyruvate, and ammonia (Eq. 1).

Because the enzyme also catalyzes the reverse reaction (Eq. 2) and the β-replacement reaction of L-tyrosine with phenol derivatives (Eq. 3), it did not take long for the application of these reactions in the synthesis of L-tyrosine and L-dopa.

Subsequently, similar reactions were found to be catalyzed by several pyridoxal phosphate dependent enzymes, such as tryptophanase, cysteine desulfhydrase, and 3-chloro-D-alanine chloride lyase. These enzymes were then successfully used to synthesize L-tryptophan and 5-hydroxy-L-tryptophan, L-cysteine, and D-cysteine [169 – 171] (see Table 12). These reactions can be summarized as follows:

$$\mathrm{L\,(D)-RCH_2CH\,(NH_2)\,COOH+H_2O} \rightarrow \mathrm{RH+CH_3COCOOH+NH_3}$$

$$\mathrm{L\,(D)-RCH_2CH\,(NH_2)\,COOH+R'H} \rightarrow \mathrm{L\,(D)-R'CH_2CH\,(NH_2)\,COOH+RH}$$

$$\mathrm{R'H+CH_3COCOOH+NH_3} \rightarrow \mathrm{L\,(D)-R'CH_2CH\,(NH_2)\,COOH+H_2O}$$

where for β-tyrosinase R = hydroxyphenyl, –OH, –SH, –Cl and R′ = hydroxyphenyl; for tryptophanase R = indolyl, –OH, –SH, –Cl and R′ = indolyl; for cysteine desulfhydrase R = –SH, thiol radicals, –Cl and R′ = –SH, thiol radicals; and for 3-chloro-D-alanine chloride-lyase R = –Cl, – SH, thiol radicals and R′ = –SH.

These successful examples demonstrate the importance of reassessing the capabilities of well-known enzymes or reactions.

Table 12. Synthesis of L-tyrosine, L-tryptophan, L-cysteine, D-cysteine, and related amino acids by pyridoxal phosphate-dependent enzymes

Product	Yield,		Substrates	Reaction
	g/L	mol%		Enzyme Microorganism
L-Tyrosine	58	88 [a]	sodium pyruvate ammonium acetate phenol	reverse of α,β-elimination β-tyrosinase *Erwinia herbicola*
L-Tyrosine	53.5	78 [b]	D,L-serine ammonium acetate phenol	β-replacement β-tyrosinase *Erwinia herbicola*
L-Dopa	58.5	[f]	sodium pyruvate ammonium acetate pyrocatechol	reverse of α,β-elimination β-tyrosinase *Erwinia herbicola*
L-Dopa	53	71 [c]	D,L-serine ammonium acetate pyrocatechol	β-replacement β-tyrosinase *Erwinia herbicola*
L-Tryptophan1	00	100 [d]	sodium pyruvate ammonium acetate indole	reverse of α,β-elimination tryptophanase *Proteus rettgeri*
5-Hydroxy-L-tryptophan	23.3	57 [e]	sodium pyruvate ammonium acetate 5-hydroxyindole	reverse of α,β-elimination tryptophanase *Proteus rettgeri*
L-Cysteine	50	88[f]	3-chloro-L-alanine sodium sulfide	β-replacement cysteine desulfhydrase *Enterobacter cloacae*
D-Cysteine	22	88[g]	3-chloro-D-alanine sodium hydrogensulfide	β-replacement 3-chloro-D-alanine chloride lyase *Pseudomonas putida*

[a] Based on sodium pyruvate.
[b] Based on D,L-serine.
[c] Based on indole.
[d] Based on 5-hydroxyindole.
[e] Based on 3-chloro-L-alanine.
[f] Based on 3-chloro-D-alanine.
[g] Sodium pyruvate was added at 2-h intervals to maintain a concentration of 5 g/L for 48 h.

6.6.1.2. Finding Suitable Enzymes

Occasionally a synthetic scheme has been designed but suitable enzymes or conversion processes are yet unknown. In such a case, it becomes necessary to assay suitable microbial strains or enzymes (as described in Section 6.6.2) as to their suitability for catalyzing the desired reaction. The production of L-lysine from D,L- α- amino- ε-caprolactam (ACL) is another typical example [172]. This process was designed to utilize cyclohexene, a major byproduct of nylon production. In this process, the biocatalyst is required to hydrolyze only the L-form of α-amino- ε-caprolactam (L-ACL) to yield L-lysine (Fig. 23).

Figure 23. Hydrolysation of the L-form of -amino- -caprolactam (l-ACL) to yield L-lysine

Two microorganisms were found during the assay: one of them hydrolyzes the L-form of the substrate and the other racemizes the remaining D-form. As a result, all the α-amino- ε-caprolactam is converted into L-lysine without requiring any optical resolution.

6.6.1.3. Substrates

Any substrate is theoretically suitable for biotransformations, provided the substrate molecules come into contact with the enzyme. Even gases, such as methane, are suitable substrates; they are bubbled into the reaction medium. The substrate should be soluble in the medium and able to pass through the cell membrane unless the reaction is catalyzed by cell-free enzymes. The substrate is usually added to the reaction medium, neat or as a concentrated solution. Sterilization of the substrate is recommended prior to its use, if required.

Only dissolved substrate is converted. Therefore, slightly soluble substrates must first be dissolved and the products may then crystallize from the solution after conversion:

$$\text{Substrate (solid)} \rightleftharpoons \text{Substrate (solution)}$$
$$\rightleftharpoons \text{Product (solution)} \rightleftharpoons \text{Product (solid)}$$

For example, powdered cortisol in concentrations up to 500 g/L is converted to crystalline prednisolone with a good yield by *Arthrobacter simplex* [173]. Substrates may also be dissolved in water-miscible organic solvents. The lower alcohols, acetone, dimethylformamide, and dimethylsulfoxide are suitable solvents. Surfactants may also be used to disperse the substrate. The combination of water-miscible solvents and surfactants may offer some advantage. In some cases, chemical modification of the substrate may improve its solubility.

An example for a process using substrate with poor solubility is the regioselective oxidation of the *tert*-butyl group of terfenadine using *Cunninghamela blakesleana* in a whole-cell biotransformation [174]. Due to its low solubility in water, microcrystalline terfenadine is solved in the water-miscible organic solvent dimethylfomamide prior to its addition to the aqueous reaction medium. This regioselective oxidation was studied as a biocatalytic alternative for the chemical synthesis of the antihistaminic drug fexofenadine.

In cases where the cell membrane is impermeable to the substrate or a cell-free or purified biocatalyst is required, the permeability of the cell must be improved, respectively, the cell wall has to be disrupted. This is accomplished by air drying, acetone drying, lyophilization, autolysis, lysozyme digestion, surfactant treatment, osmotic shock, freezing and thawing, or ultrasonic treatment. For cell-free preparations, the cell debris can be removed by centrifugation or microfiltration.

If the substrate does not suit the desired conversion, its chemical modification should be considered. Addition, variation, or removal of a protecting group or modification of a functional group in the substrate molecule sometimes makes its interaction with the enzyme more efficient. In addition, these modifications may prevent undesirable side reactions or degra-

dation. This method is frequently used in steroid conversions. A systematic assay for a suitable chloroacetoacetate ester for enantioselective reduction yielding the L-form of 4-chloro-3-hydroxybutanoate, a promising precursor for the chemical synthesis of L-carnitine, is an example [175].

6.6.1.4. Media

Besides performing biocatalysis in aqueous media, there has developed the so-called "nonaqueous enzymology" which has become an important area of research and development during the last decades [176]. Enzymes exhibit a wide array of novel reactivities and selectivities in nonaqueous solvents. For example, many reactions that are impossible in water due to kinetic or thermodynamic reasons can be performed in organic solvents, [163, 164, 177] due to the suppression of water-induced side reactions. Improved and altered substrate specificities [178, 179] and selectivities can be observed. Examples of practical applications are enantioselective synthesis [180], chiral resolution [181], and combinatorial biocatalysis [182]. The possibility of the solubilization of hydrophobic substrates or products in organic solvents opens opportunities for the enzymatic production of poorly water-soluble fine chemicals and pharmaceuticals. The thermal and storage stability of enzymes can be significantly enhanced in nonaqueous media [164, 176, 178].

6.6.2. Selection of Biocatalysts

More than 8000 enzymes are known [125]. Almost all types of chemical reactions which are also catalyzed by normal chemical catalysts are involved. According to the desired type of conversion and the classification of the enzymes one can easily determine which enzyme would be suitable for the desired conversion by inspecting the enzyme catalogue published by the committee [125]. However, the properties of enzymes from different sources may vary widely, even if they catalyze the same reaction. Therefore, testing is indispensable. A wide variety of biocatalysts are tested for the purpose of determining their ability to carry out the desired reaction. Such a test, also called *screening*, may be one of the most important steps for a successful biocatalytic conversion.

6.6.2.1. Screening

Kitahara and co-workers [183] screened bacterial strains from cultures grown aerobically at 30–37°C in nutrient broth containing malt extract. Sodium fumarate and ammonium chloride were added 24 h after growth started. After incubation for another 24 h the L-aspartate in the culture broth was analyzed by chromatography. A strain of *E. coli* was selected by this screening as the most promising producer of aspartase. Under suitable reaction conditions, 56 g of L-aspartate was produced per 100 mL with a molar yield of 99 % by using 1 g of dried cells. Subsequently, this process was developed into large-scale technology by which L-aspartate was synthesized continuously with *E. coli* cells immobilized on κ-carrageenan [184].

The screening procedure described above may be rather simple, but it reflects the essence of screening. Normal screening procedures can be more complicated and deal with a great variety of microorganisms, including bacteria, actinomycetes, molds, yeasts, and basidiomycetes.

6.6.2.2. Enrichment

Another method to find a suitable biocatalyst can be *enrichment*. Sometimes it is desired or necessary to find biocatalysts capable of performing a specific conversion from natural sources. Soil samples containing mixed microbial populations are rich sources of test organisms. Because the enzymes in these microorganisms modify or degrade a great variety of complex organic compounds, at least one of the microorganisms is expected to offer one or several enzymes that perform the desired conversion. These microorganisms are selected using the *enrichment technique*. A typical enrichment procedure is the isolation of bacterial strains that perform the asymmetric hydrolysis of D,L-2-amino- Δ^2-thiazoline-4-carboxylic acid (D,L-ATC), an intermediate of D,L-cysteine synthesis, to L-cysteine [185]. Soil samples were incubated in a medium containing 0.3 % D,L-ATC as the sole

nitrogen source. After spreading each culture on a plate of the same medium, colonies that appeared were isolated and grown on nutrient agar containing 0.2 % D,L-ATC as the enzyme inducer. The resulting cells were then transferred to a solution containing 1 % D,L-ATC and the formation of L-cysteine was demonstrated by chromatographic or microbiological methods. Among 1975 colonies from 388 soil samples, 31 L-cysteine-producing bacteria were isolated. One of them, *Pseudomonas thiazolinophilum*, was mutagenized. Mutants with inhibited L-cysteine metabolism were screened from the mutagenized cultures. One of these mutants converted the added substrate almost stoichiometrically to L-cysteine with a yield of 31.4 mg/mL [186].

The enzyme system of *Pseudomonas thiazolinophilum* hydrolyzes D,L-ATC in two steps as shown in Figure 24.

Figure 24. Asymmetric hydrolysis of D,L-2-amino- 2-thiazoline-4-carboxylic acid (D,L-ATC) to L-cysteine

Although screening sometimes is regarded as old-fashioned, time-consuming, and even illogical, some consider it to be one of the most promising methods for finding new genes in microorganisms.

6.6.2.3. Molecular Engineering

Sometimes enzyme yields in wild-type organisms are low or the desired enzyme is not found in the available microorganisms. In this case, molecular engineering techniques can lead to an enzyme catalyzing the desired reaction. There are two different strategies that represent the "state-of-the-art" technologies: *rational design* and *directed evolution* [153]. Both technologies require different knowledge of the target enzyme as well as laboratory equipment (Table 13).

Table 13. Requirements and molecular methods for rational design and directed evolution technique

	Rational design	Directed -evolution
Requirements:	3D structure of the target enzyme	high-throughput-screening/selection technology to analyze enzyme properties
	knowledge of reaction mechanism	
	modeling of enzyme-substrate interaction	
Molecular methods:	site-directed mutagenesis	random mutagenesis

6.7. Improvement of Conversion Processes

After an adequate process has been designed, it must be optimized. This includes improvement of the strain and the search for optimal growth (highest enzyme yield and maximum activity) and optimal reaction conditions.

If the enzyme to be used is constitutive, the amount of biomass containing that enzyme will have to be increased. This is usually sufficient because the constitutive enzyme is formed independently of the medium composition. However, if the enzyme is inducible, an effective inducer, which may be the substrate itself or another structurally related compound, will be required. If the enzyme is repressive, the repression factor will either have to be eliminated or the repressive compounds, which may be present in the growth medium or formed during the growth, must be removed.

Catabolites of an easily metabolizable carbon source, e.g., glucose or sucrose, and the end product of a metabolic pathway usually cause catabolite or product repression, respectively. Therefore, the composition of the growth medium, growth period, and various physical parameters of growth, such as temperature, aeration, agitation, and pH, must be carefully controlled. In successful cases, the concentration of the required enzyme reaches more than 10 % of the total soluble protein [187].

Optimal physical and chemical conditions for the biotransformation itself must be determined with the same care as for the optimization of growth conditions. This is especially important

if side reactions are observed, because they decrease product yield and make product isolation difficult. Physical or chemical treatment of the biocatalyst, such as heating, pH change, and the addition of detergents, organic solvents, or specific inhibitors may cause specific inactivation of undesired enzymes. For example, the *trans-N*-arabinosylation of adenine from synthetic uracil arabinoside (Fig. 25) yields adenine arabinoside, an antiviral agent.

Figure 25. *trans-N*-arabinosylation of adenine from synthetic uracil arabinoside

This reaction is catalyzed by cells of *Enterobacter aerogenes* and takes place only at temperatures above 60°C [188]. The reaction does not proceed below 50°C because hypoxanthine is formed by adenine deaminase before the *trans-N*-arabinosylation by two kinds of nucleoside phosphorylases takes place. Fortunately, these phosphorylases are still active at 60°C, whereas the deaminase is completely inactivated at this temperature. Other examples are summarized in Table 14.

In the case of immobilized biocatalysts, concentration gradients of substrates and products may occur that could lead to decreased biotransformation rates. These gradients can be reduced by decreasing the *Thiele modulus*, e.g., by using smaller carrier particles or by reducing the diffusion distance between the free solution and the immobilized enzymes.

Microbial conversion can also be optimized by improving the selected strain. Standard methods of strain improvement include the isolation of single colonies, optionally after mutagenesis, and screening of the best suited isolates. Such conventional genetic manipulation techniques have been developed during the last decades for the improvement of useful strains. Recombinant DNA technology is providing new prospects for strain improvement. Plasmid or phage vectors can transfer DNA fragments of microbial, plant, animal, or even synthetic origin into a suitable recipient microorganism. These gene cloning techniques are still restricted to microbial strains such as *E. coli, B. subtilis*, and *S. cerevisiae*, in which the genetic background and the appropriate host–vector systems are well known, but their practical application is rare [191]. However, this technology will undoubtedly provide one of the most important keys for the future development of microbial conversions.

6.8. Conclusion and Outlook

Biocatalysts have become one of the most important tools in nearly all fields of industrial biotechnology. The main advantages of using biocatalysts are their unique properties such as high chemo-, regio-, and stereoselectivity and the ability to catalyze reactions under mild conditions.

During the last couple of years, many new methods and techniques have been developed to overcome common problems. Some examples here might be molecular engineering techniques such as rational design or directed evolution to increase low biocatalytic activities [153], biocatalysis in nonaqueaous reaction media to bypass solubility problems of substrate and/or product [179], or the applications of high-throughput screening methods for the search of new and suitable biocatalysts. Another field of interest that will become of great impact is "metagenomic research" that will enable scientists to find new biocatalysts with desired qualities [192].

To make new biocatalysts attractive for industrial applications they have to be available in sufficient amounts. High expression rates of enzymes can be achieved by genetical and physiological manipulations of the expressing mi-

Table 14. Elimination of side reactions by physical or chemical treatment

Desired reaction	Side reaction	Treatment	Reference
Ammonium fumarate → L-aspartic acid (*Escherichia coli*/aspartase)	fumaric acid → L-malic acid	incubation of culture broth at pH 5 and 45 °C for 1 h	[149]
Fumaric acid → L-malic acid (*Brevibacterium ammoniagenes*/fumarase)	fumaric acid → succinic acid	treatment of immobilized cells with 0.6 % bile extract	[148]
L-Aspartic acid → L-alanine (*Pseudomonas dacunhae*/aspartate β-decarboxylase)	L-alanine → D-alanine	incubation of culture broth at pH 4.75 and 30 °C for 1 h	[149]
Cholesterol → 1,4-androstadiene-3,17-dione (*Arthrobacter simplex*/multistep conversion)	further decomposition of the sterol molecule	addition of α,α'-dipyridyl (1 mM) to the culture broth	[137, 189]
β-Sitosterol → 17-ketosteroids (*Nocardia* species/multistep conversion)	further decomposition of steroid ring	addition of α,α'-dipyridyl (0.3 mM) to the conversion mixture	[190]
D,L-2-Amino-Δ^2-thiazoline-4-carboxylate → L-cysteine (*Pseudomonas thiazolinophilum*/multistep conversion)	further degradation of L-cysteine	addition of hydroxylamine or semicarbazide to the reaction mixture	[186]

croorganism such as optimizing the number of plasmids per cell or inactivation of "negative" cell functions (e.g., deletion of protease coding genes). Apart from deleting unwanted side activities also novel metabolic pathways can be implemented. These microorganisms, customized only to fulfill special needs for biocatalytic applications, are called "designer bugs" or "tailor-made microorganisms".

7. Downstream Processing

Downstream processing is one of the most underestimated steps in bioprocesses and it is well known especially in the pharmaceutical industry that downstreaming is the most expensive and unfortunately the most ineffective part of a bioprocess. Thus, one can assume that new developments are widely described in the literature. Unfortunately, this is not the case. Only a few working groups focus on new and more effective procedures to separate products from fermentation broths or biotransformations. A chief characteristic of biotechnology is the wide variety of products. Due to this variety, a broad spectrum of separation techniques must be applied. However, for nearly all products one starts with a dilute suspension and tries to produce a highly purified dry product. In the case of extracellular products, the solids in this suspension may include intact organisms, other insoluble fractions of the medium or natural sample, and perhaps insoluble products. Concerning intracellular products the solids include in addition fragmented mycelia caused by cell disruption, which is necessary to gain the products. According to this starting point, nearly each downstream process consists of the four following steps [193]:

- Removal of insoluble particles
- Isolation of the product
- Purification
- Polishing

With respect to downstreaming in laboratory scale, one is normally only limited by the available equipment. However, with regard to upscale processes one should have in mind that the developed process should also be applicable in industry. Thus, Belter et al. [193] have formulated the following questions, which are also crucial to biotechnology downstream processes:

- What is the value of the product?
- What is the acceptable product quality?
- Where is the product in each process stream?
- Where are the impurities in each process stream?
- What are the unusual physicochemical properties of the product and the principal impurities?
- What are the economics of various alternative separations?

In addition, it is important to use materials which are available for all upscale processes, since the downstream behavior of the product may change while changing, for example, the type of chromatographic resin or membrane material. Normally the recovery costs exceed the bioprocess costs; however, some upstream parameters influence the downstream processing:

– The characteristic properties of the producing microorganism or cell line
– The location of the product
– The stability of the product
– Byproducts and impurities
– Concentration of the product in the medium from which it is to be recovered

A general downstream scheme based on these parameters is given in Figure 26.

Figure 26. General downstream scheme in biotechnology

The main aims of the primary separation step are to achieve a volume reduction and to make a first stage purification of the product by removing dissimilar components from the broth. The most important techniques in use are:

– Membrane processing
– Ion exchange chromatography

In the membrane process, ultrafiltration and reverse osmosis are often used for separation, concentration, and desalting. In addition, polar membranes are used for ion exchange and desalting. Ion exchange chromatography is applied in order to remove either major contaminants from the broth or the desired product from the broth. Chromatographic procedures – based on columns or membranes – are also often used in the purification step. Other techniques in this part of the downstream process are precipitation and liquid–liquid extraction.

7.1. Sample Disruption

The influence of the sample disruption step in upstream and downstream processes cannot be ignored. The disruption is dependent on the properties of the sample. The main focus of the disruption is always to release as much as possible of the product. However, depending on the mechanism, parts of the product may be destroyed during the disruption process. Thus, very effective and short procedures are required. A distinction can be made between mechanical, chemical, and enzymatic procedures for product release. Mechanical methods are often preferred because of short residence time, lower operating costs, and contained operation [194]. The most common mechanical means of disruption are:

– Homogenizers [195, 196]
– Bead mills [196].

A *homogenizer* consists of a positive-displacement pump, which supplies the liquid sample at high pressure through a small nozzle or an orifice valve. The disruption results from the combination of shear force and impingement on the valve. Bead mills use horizontal grinding chambers filled with glass beads or other resistant materials such as zirconium oxide, zirconium silicate, titanium carbide, etc [197]. The dispensed sample is introduced into the grinding chamber on a continuous basis. The level of

disruption depends on the variable turning speed of the bead mill.

By using *bead mills*, cell disruption can be achieved in a single run with better temperature distribution and temperature control. Another possibility for cell disruption or at least product liberation is the use of microwaves or ultrasound which can be combined with sample extraction by organic solvents. Microwave techniques are widely used in acid digestion of solid samples. Their use in the extraction of organic analytes from environmental samples is less widespread, despite the availability of commercial devices for this purpose and their potential for reducing analysis time and solvent consumption.

A possibility for cell lysis under very mild conditions is the use of *hydrolyzing enzymes*. In addition, enzymes offer selectivity during product release. Enzymes hydrolyse the walls of cells, and when sufficient wall has been removed, the internal osmotic pressure bursts the periplasmic membrane allowing the intracellular components to be released [195]. The effect of lytic enzymes is specific to particular groups of cell types, which is attributed to the differences in cell wall composition. For example, the most efficient lytic enzyme for bacteria is lysozyme from hens' egg. This enzyme is also used in large-scale processes for enzyme production [198]. Even more highly specialized procedures for sample disruption can be applied in biotechnology. For example, high yields of intracellular enzymes from yeast can be obtained by applying a series of electric field pulses [199]. By using this technique, up to 90 % of the total activity can be released without any further or previous treatment of the cells. The method is based on electroinduced changes in the cell envelope leading to a leakage of part of the intracellular proteins without the formation of debris and permits the treatment of large volumes.

7.2. Solid–Liquid Separations

Solid–liquid separation is a very important procedure during downstream processing in biotechnology for cell separation, cell debris removal, and also for product recovery. The most important solid–liquid separation techniques in use for are filtration and centrifugation. Filtration separates solids from a liquid by forcing the liquid through a solid support or filter medium. Dead-end filtration and cross-flow filtration are two different designs of filtration which can be used. In *dead-end filtration* mode, the total process fluid stream flows through the membrane. The retained solids accumulate on the membrane and build up a filter cake. The membrane has to be changed when the membrane pores are clogged by the solids. When the feed flow is directed parallel to the membrane surface, the term *cross-flow filtration* is used. The tangential flow of liquid removes any retained molecules or particles from the membrane surface, which results in a stable flux for a longer time period. By using cross-flow filtration, relatively low shear stress is possible and filter aids are not required. In addition, scale-up is simple and cell washing is possible in a single process step.

Over the last 30 years, a number of further membrane processes have been developed for molecular separation. These filtration techniques can be divided into four major groups: reverse osmosis (hyperfiltration, RO), nanofiltration (NF), ultrafiltration (UF), and microfiltration (MF) [200]. Membrane processes are easy to scale up and the possibility of using the same materials and configurations in different sizes from laboratory to process scale reduces the validation effort enormously. However, filtration processes are limited with regard to selectivity. The fractionation of proteins can only be achieved with large differences in the molecular weight of the proteins and it is important to keep in mind that a certain difference in the molecular weight of two proteins does not mean the same degree of difference in molecular size. Proteins that differ in molecular weight by 10 times may differ in size by only 3 times when in globular or folded form. Another problem encountered when using membrane processes for product recovery can be the slow retentate flux, which can result in the formation of a thick secondary membrane. Another possibility is the strong interaction of the sample with the membrane material. This often depends on unspecific protein adsorption which is affected by several factors [201]. Thus, different membrane types have to be screened to minimize the unspecific binding of the sample when a new filtration procedure has to be developed.

7.3. Product Recovery

One of the most important procedures in product recovery are chromatographic processes. During chromatographic steps the sample is separated into several fractions according to interactions between the different molecules in the liquid phase and the stationary phase (chromatographic resin). The molecules can be separated according to their size and/or charge and based on hydrophobic/hydrophilic or affinity interaction with the stationary phase. Column chromatography utilizes a vertical column filled with the solid support with the sample to be separated placed on top of this support. The rest of the column is filled with a solvent (eluent) which, under the influence of gravity, moves the sample through the column. Differences in rates of movement through the solid medium are translated to different exit times from the bottom of the column for the various elements of the original sample. Based on the specific interactions between the sample in the mobile phase and the stationary phase the column chromatography can be performed as:

- Ion-exchange chromatography,
- Size-exclusion chromatography (gel-filtration chromatography),
- Reversed-phase chromatography, and
- Affinity chromatography.

Immobilized-metal-ion affinity chromatography (IMAC) as a special form of affinity chromatography is a popular and powerful way to purify proteins. It is based on the specific coordinate covalent binding between histidine or other unique amino acids and various immobilized metal ions (e.g., nickel).

Most of the chromatographic systems are run in a batch or quasicontinuous mode. Nowadays, new developments such as simulated moving bed chromatography [202] and anular chromatography [203] offers the possibility of continuous processes. One problem in column chromatography are the difficulties in upscaling. If the column radius is increased, unless special packing techniques are employed, the packing procedure becomes inefficient and the packing itself unstable. In addition, to maintain the optimum mobile phase velocity, the flow rate will need to be substantially increased and the consumption of mobile phase will eventually become economically impractical. Conversely, if the column length is increased, then the impedance to flow will become greater leading to high column pressures. If large column radii are employed, then the mechanical strength of the column system will limit the maximum permissible pressure. Consequently, lengthening the column will eventually require the particle diameter to be increased to provide adequate permeability. Increased particle diameter will, in turn, reduce the column efficiency, which may impair the resolution of the compounds of interest [204].

Membrane. Until today, the required process steps for the product recovery are carried out separately, which leads to many energy-intensive process steps such as filtration or chromatography and production of vast wastewater amounts, respectively. Membrane adsorption allows the integration of several process steps into one-unit operation, which means the downstreaming of biotechnologically produced proteins can be carried out by saving process time and resources [205, 206]. In addition to this, conventional chromatographic techniques which are based on packed columns often require lengthy procedures. This can lead to the degradation of sensitive proteins [207]. Furthermore, packed columns exhibit a high pressure drop across the column and a slow diffusion-controlled binding process of solutes within the matrix [208]. Whereas membrane systems show several advantages to packed columns, most important, mass transfer takes place through convection rather than through diffusion. Due to this fact, membrane adsorbers enable a time-effective performance with high flow rates without high back pressure [209]. Membranes can be converted into efficient adsorbers by attaching functional groups to the inner surface of synthetic microporous membranes. Affinity adsorption, ion exchange, or immobilized-metal affinity chromatography can be carried out by these membranes. Membrane ion exchangers of strong acidic (sulfonic acid), strongly basic (quarternary ammonium), weakly acid (carboxylic acid), and weakly basic (diethylamine) types are commercially available. A chelating membrane based on the iminodiacetate (IDA) group is applicable for IMAC. Membrane adsorber technology has several major advantages compared to classical separation methods. Due

to the membrane structure, the binding of proteins is not limited by diffusional processes, therefore loading and elution can be performed at very high fluxes resulting in very short cycle times. Compressibility of the membrane under normal operation conditions can be neglected, channeling cannot occur, and the pressure distribution inside the modules is designed to have plug flow through the module, all of which lead to sharp breakthrough curves. Scale-up is very easy, materials and systems allow cleaning in place (CIP), and the validation of the process is made easier due to of standard products and validation service of suppliers.

7.4. Solvent Extraction

Solvent extraction is the most common method for the recovery of hydrophilic substances and, therefore, a method for separating well-soluble metabolites from cultivation media. Classical extraction processes use organic solvents, which are often rarely suitable for effective recovery of the solute. Recently, new extractions have been developed which form specific adducts with the metabolite in question and allow its recovery with high efficiency and selectivity [210]. Solvent extraction in biotechnology focuses on the recovery both of primary metabolites (e.g., ethanol, acetic acid, citric acid, and amino acids) and of secondary metabolites (e.g., antibiotics or vitamins). The concentration of secondary metabolites is usually much lower than that of primary metabolites. Since most secondary metabolites are for use as therapeutics, the quality requirements of the products are high. Solvent extraction can help to fulfill these requirements. In addition, the set-up of integrated bioprocesses (production and downstreaming) can be performed by solvent extraction [211]. Supercritical fluid extraction (SFE) becomes also an important tool in biotechnological downstream processing since it offers important advantages compared with other solvent extraction methods. It is possible to work in an oxygen-free system, which prevents oxidation. The low temperatures applied minimize thermal degradation and microbes or their spores are not soluble. In addition, supercritical fluids for extractions are inexpensive. The successful implementation of this technique can lead to improved sample throughput, more efficient recovery of analytes, cleaner extracts, economic replacement of halogenated solvents, and a high level of automation, compared to conventional sample preparation procedures [212]. Supercritical fluid processes are being commercialized in the polymer, pharmaceutical, specialty lubricants, and fine-chemicals industries. Supercritical fluids are advantageously applied to increase product performance to levels that cannot be achieved by traditional processing techniques.

8. Monitoring and Modeling of Bioprocesses

The requirement to operate biotechnological processes in a cost-effective manner by simultaneously maintaining a high product quality and safety is becoming increasingly relevant. Historically, the most important means of achieving increased productivity from bioprocess plant has been through time- and resource-consuming experimental developments. More recently, however, significant advances have been made in the area of computer applications for bioprocess supervision, modeling and control, and their introduction in process industry.

Typically, little use is made of the large amounts of bioprocess online and laboratory assay data after an experiment is completed. Recently, attempts have been made using enhanced automation strategies to improve the quality of information presented to operators and increase the level of automatic process supervision, although few industrial applications have yet been reported. On a plantwide perspective, the scheduling of process operations is also traditionally manually undertaken by experienced personnel by using a trial and error approach with a planning board. This also appears to be a potential area for modern bioprocess management.

Knowledge-based systems, such as fuzzy logic systems, can be designed to cope with uncertainty and allow the coupling of quantitative information with the qualitative or symbolic expressions (in the form of heuristics), so as to reproduce the actions of an experienced process operator. They might therefore be used as an intelligent, online virtual assistant to the process

operator, or, with extra knowledge as a supervisor in running and maintaining bioprocess operations within optimal operating conditions. The main objective in this approach is to develop an expert supervisory system which uses bioprocess and control knowledge in the form of rules in conjunction with bioreactor state estimation (soft sensing), parametric identification and process control algorithms running in real time. In addition, provision needs to be made for process models and known bioprocess behavioral characteristics to be incorporated in order to enhance the overall supervisory control strategy. The complete system aims to perform process monitoring, process control, sensor validation, fault detection, and diagnostic tasks and, in addition, provide recovery advice so as to achieve continuous online optimization.

Collateral with the above approach is the online determination of the critical key variables which govern process production. The measurement and estimation problems are well known and represent the main drawback concerning an effective biosystem optimization. Three ways of reducing the difficulties encountered can be proposed:

- Better sensors
- Better sampling and automatic analysis systems
- Online estimation of difficult to measure, or immeasurable, variables.

Although all of these are attracting research effort, the techniques of online state and parameter estimation are receiving the greatest interest. Whilst developments in biosensors are in some cases helping to contribute to the online determination of bioprocess parameters, they are by no means at the stage where general applicability has been achieved. Until this is the case, the development of online estimation techniques will provide the major means by which online closed loop feedback control of critical bioprocess variables can be achieved.

Several different approaches can be adopted in the development of bioprocess estimation algorithms. The easiest but potentially least accurate way of obtaining an estimate of a "difficult to measure" primary process variable is to establish a correlation with a measurable secondary process variable, whilst ignoring measurement errors, noise, etc. A more robust approach might be to adopt a numerical estimation technique, either for estimating the parameters of a predefined model structure, usually of a generalized linear time series form, or directly to obtain an estimate of a difficult to measure primary process variable (state estimation or software sensor). An alternative approach is to exploit the nonlinear mechanistic structure of the bioprocess, if known, in the form of a state observer.

Neural Computing. A relatively new development in artificial intelligence is the area of neural computing. Neural networks are dynamic systems composed of highly interconnected layers of "simple" neuron-like processing elements. In the field of process engineering, it is their ability to capture process nonlinearities which offers potential benefits. Other useful characteristics are their ability to adjust dynamically to environmental and time-variant changes, to infer general rules from specific examples and to recognize invariances from complex, high-dimensional data. These properties provide neural networks with the potential to outperform other "learning" techniques. Given a series of experimental data the network is able to establish the governing relationships in these training data. This ability can be exploited to aid the nonlinear modeling, control, and optimization of complex processes, as well as being used in existing predictive control methods.

8.1. Characteristics of Bioprocesses

8.1.1. System Definition

A biotechnological process consists of a system of chemical, biochemical, and microbiological reactions, incorporating process-engineering aspects such as mass and energy conservation, thermodynamics, or heat and mass transfer correlations. (Fig. 27). The biological part of the system represents the peculiarity of the system characteristics and causes the great difficulties in considering it from the system theoretical point of view.

Common for all system models is their mapping of inputs to outputs, of stimuli to responses in some with the additional introduction of state variables. Therfore, the task is to define proper inputs and outputs, dependent on the problem

Figure 27. General model structure for biotechnological processes
x = external flow and transport rates; c = concentration of the component $(\cdot)^I$ inlet, $(\cdot)^O$ outlet; TR = transfer rates; Q = volumetric reaction rate; q = specific reaction rate; Y= yield coefficient; r = intrinsic reaction rate; $(\cdot)_i$ = index for quantity i; $(\cdot)_j$ = index for quantity j

available, to use appropriate signals (trajectories) to describe the system behavior in their important aspects and to build up the model.

A biotechnological system can be defined as a set of *i* biochemical reactions involving *m* input variables $\vec{x}(t)$, *o* output variables $\vec{y}(t)$, *m* state variables $\vec{z}(t)$ and *r* parameters $\vec{p}$ notated in operator transformation *T(·)*:

$$\vec{z}(t) = T\left(\vec{x}(t), \vec{p}\right) \tag{1}$$

$$\vec{y}(t) = T^*\left(\vec{x}(t), \vec{z}(t), \vec{p}\right) \tag{2}$$

with

$$\begin{aligned} \vec{z}(t) &= \left[z_1(t) \quad z_2(t) \quad \ldots \quad z_n(t) \right]^T \\ \vec{x}(t) &= \left[x_1(t) \quad x_2(t) \quad \ldots \quad x_m(t) \right]^T \\ \vec{y}(t) &= \left[y_1(t) \quad y_2(t) \quad \ldots \quad y_o(t) \right]^T \\ \vec{p} &= \left[p_1 \quad p_2 \quad \ldots \quad p_r \right]^T \end{aligned} \tag{3}$$

The model does not determine the input variables $\vec{x}(t)$. They represent the systems stimuli and can be divided up into control variables and

random forcing functions. Control variables are those which are chosen by the operator to manipulate the system in such a way the benefits are maximized. Typical examples in bioprocess engineering are: temperature trajectories, agitation rate, or feed rate of key components. Random forcing functions can be seen as outer disturbances of the system whose origin comes from the system environment and not from internal uncertainties, e.g., impurities of the inoculums or the feed medium. To evaluate the system dynamics, it is important to define meaningful trajectories of the control variables. Keeping the values constant will not result in a representative information retrieval of the biosystem. Only if characteristic curves – or specific combinations – are chosen to which the system reacts sensitive a representative process description is possible. Therefore, it is evident that the experimental as well as the theoretical design must be performed from deep problem awareness.

The state variables $\overrightarrow{z}(t)$ represent storage elements for mass quantities (e.g., substrate, products, biomass, inhibitors, interferences), information, or energy of the system. The state vector $\overrightarrow{z}(t)$ is composed of any set of quantities sufficient to completely describe the behavior of that system. Given a state vector at a particular point in time and a description of the system forcing functions, in an appropriate uncertainty formulation, and control functions from that point in time forward, the state at any other time could be computed. In biotechnological processes state variables are frequently defined, if the key quantity of interest can not measured directly and must therefore determined by state estimators from other process variables [213, 214]. The introduction of state variables is not strictly necessary. But in their absence inner relation can only be hardly understood and described. Also a direct mapping of an input vector to an output vector without consideration of state quantities in form of a signal model, as it is typical in conventional signal analysis in electrical engineering, can not be accomplished. Their application depends on the point of view. A signal model provides mainly information about the behavior of changing influencing parameters and how they affect the outputs based upon given inputs. No information can be provided about the intrinsic reactions or the basic mechanism, the focus is outside of any interpretation purposes [215, 216]. Mostly, they are used for software sensors [217, 218] or optimization purposes [219, 220]. Both represent black-box applications (see below), where only the outputs are of special interests, the inner relations or interpretation aspects are secondary.

As output variables $\overrightarrow{y}(t)$, very often quantities are specified which are accessible by online measuring systems or which can be estimated by software algorithms. They can be seen as the result of a measurement model which relates the state variables $\overrightarrow{z}(t)$ to the output variables $\overrightarrow{y}(t)$. These quantities represent the values with whose the system can be evaluated. The output vector $\overrightarrow{y}(t)$ is strongly related to the aspect of observability (see below).

The division into parameters, state variables, or output variables is not an immanent property of a system, but a specific view by the analyzer of the system. It can be changed in relation to the mode of process operation, to the process targets or the simplifying assumptions of the model. A state variable z_i can be exchanged to an output variable y_i and vice versa. A mathematical system should provide a coherent description of the entire bioprocess including all relevant system aspects. The degree of complexity of the bioprocess or the possibility for a simplified modeling of some parts of the system is determined by the intended application and by the skills of the system analyzer.

Parameters $\overrightarrow{p}$ can be seen as fixed quantities of the system. In the ideal case, they should be time invariant, as it is indicated by their original definition. However, sometimes a time dependency of parameters is introduced to gain a better system description. Normally, the parameters are used to interpret the biosystem characteristics. However, the meaning of the parameters can be quite different depending on the point of view from which the biosystem is described. In terms of a mechanistic approach using fundamental physico–chemical equations, the determined parameters, after they are fitted by experimental data, have a direct physical meaning and can be used for interpretation purposes and are comparable between different experiments. If the behavior is characterized phenomenological, by means of descriptive equations, the parameters determined are only valid under the specific boundary conditions of the experiments.

They can be quite different in different experiments and possess nearly no general validity. One must be very careful when comparing different approaches upon the quantities of these parameters.

8.1.2. System Description

A biotechnological system consists in particular of a set of chemical, biochemical, and microbiological reactions whose components, reactions rates, and other characteristics as temperature, pH-value, or internal energy, are mostly not exactly known. The metabolism of the biological unit is a very complicated process, not only because the intracellular reaction network may be quite complex, but also due to the large number of inner relations, control loops on reaction level, regulatory mechanism, and genetic level that are overlaid to coordinate the elementary reactions. So even when the microkinetics could be measured exactly, it would be impossible to establish a correct system map in every detail without the introduction of rigorous simplifications. Another reason for uncertainty is the inhomogenity of the units (e.g., cells) in the whole ensemble, which is normally not considered when characterizing biosystems. The relations are not constant and vary with time. Furthermore, there might be a morphological differentiation biological unit which is accompanied generally by changes in the dynamic behavior.

Therefore, the interesting question is why these complex systems can often be described for specific process targets by a few mathematical equations only. One reason is that the functional blocks of the biosystem operate together in a network of regulation, and exchange of mass, charge, and energy and a few bottleneck processes determine the behavior of the whole system. Another reason is the tremendous number of units in the ensemble of a biosystem which hides individual variations in their growth and leads to a smoothed average behavior. In most cases, the problem shifts. It is not the difficulty to build up the equations, but it is hardly to determine the characterizing parameters, which are generally dependent on time and other system state quantities. Furthermore, a few reactions can already determine the rates of many others. When the main inputs and the final overall outputs are known, a prediction is often even possible with incomplete information on the involved intracellular reaction network [221 – 223].

For analysis and design of those systems, two aspects have to be considered – the biological reactions catalyzed by the bioactive compound, and the numerous chemical and physical processes which precede, accompany, and follow them. Within the biosystem, the most important physical processes, which are intimately bound to the biological reactions, are associated with transport of material, energy, and information to and from the location of the bioactive unit. The dependency of the biological reactions on the microenvironment around the unit is called *microkinetics*. Due to the transport phenomena, the microenvironment will vary along different locations in the systems. The integral description of microkinetics in connection with the transport processes that may be included in a system model is called the *macrokinetics*. Ideally, one would always attempt to model the transport phenomena and the microkinetics of the model, because this model could be combined with proper reactor models to predict the macrokinetics of different biosystems. Unfortunately, at present, the effort for simulation of detailed reactor models is rather high and methods for analyzing the microenvironment of the cells are still rare. Therefore, what is usually observed is always a kind of macrokinetics. To find a compromise between these facts and our limited knowledge about the process, the description of the biological system is often characterized by means of so-called *formalkinetic* approaches. This means a formal application of system equations that represent actually microkinetics to a process, where only averaged macrokinetics can be measured. As an immediate consequence, the model parameters will change when the operating conditions of the reactor are changed, or even more, if a different reactor with changing boundary conditions is used. This necessity limits the predictive power of *formalkinetic* models for biotechnological processes significantly.

In principle, independent of the available system volume, the mass balance of a component i from the general point of view can be described using a finite volume approach solving the governing equations for fluid flow and heat and mass transfer:

$$\frac{\partial c_i}{\partial t}+div\left(c_i\ \vec{u}\right)-div\left(\Gamma\ gradc_i\right)-\frac{dc_i}{dt}=0 \qquad (4)$$

where the dependent variable is denoted by the concentration c_i and $\vec{u}$ represents the velocity. Both Γ, the diffusion coefficient, and dc_i/dt, the source term, are specific to a particular meaning of a component *i*. From this general description, a one-dimensional model can be derived. In the presented approach a dynamic process description is the goal rather than a rigorous three-dimensional simulation of a compartmented system. For describing biological systems a coupling with the involved chemical, biochemical, and microbiological reactions is necessary.

In the considered (finite) volume, homogeneous (bio-)chemical reactions system can be analyzed according to Gavalas [224]. He assumes a detailed knowledge of the chemical behavior of all the system components. The dynamic of those reaction systems is described by a set of ordinary differential equations, by using the idea that every isolated chemical kinetic system should be consistent with the conservation of atomic species and of internal energy. In principle, this approach can also consider regulatory and closed-loop effects at the component level. A general stoichiometric exact model as a closed homogeneous reaction system of constant (finite) volume can be described as follows.

$$\frac{dc_i\left(t\right)}{dt}=\sum_{j=1}^{M}k_{ij}\varphi_j\left(c_1\left(t\right),\ldots,c_N\left(t\right),T\left(t\right)\right) \qquad (5)$$

where

$(\cdot)_i$	Component *i* with *i* = 1, . . . , *N*
$(\cdot)_j$	Reaction *j* with *j* = 1, . . . , *M*
$c_i(\cdot)$	Concentrations of the different (bio-)chemical components *i*
$j_j(\cdot)$	Reaction rate of the *j*-th reaction
$T(\cdot)$	Temperature
k_{ij}	Exact stoichiometric coefficient from component *i* in reaction *j*

If we consider a reaction in a volume with possible in- and outflow, the above approach must be extended with the balances of the internal energies

$$\frac{\partial T}{\partial t}+div\left(T\ \vec{u}\right)-div\left(\Gamma\ gradT\right)-\frac{dT}{dt}=0 \qquad (6)$$

$$\frac{dT\left(t\right)}{dt}=\frac{1}{c_p}\sum_{j=1}^{M}H_j\varphi_j\left(c_1\left(t\right),\ldots,c_N\left(t\right),T\left(t\right)\right) \qquad (7)$$

where

H_j	Reaction enthalpy of *j*-th reaction
c_p	Averaged specific heat capacity of mass in the considered volume

In this model, all the components involved in the process reactions take part in the mathematical consideration. Furthermore, Gavalas assumes that the *j*-reactions are independent of each other. The mass conservation and more precisely the conservation of atomic species impose certain relations between the stoichiometric coefficients k_{ij}.

In this case, a so-called *forward problem* is considered. A forward problem is one in which the parameters and starting conditions of the system, and the kinetic or other equations which govern its behavior, are known and the equations can be solved by typical numerical methods. From a mathematical and physical point of view, it can be seen as the calculation of the "effect of a cause" and not to estimate the "cause of an effect", as it is accomplished in an inverse problem. In other words, we usually know how to use mathematics and physical reasoning to describe what would be measured if conditions were well known [225, 226]. Most mathematical models in fluid dynamics are of the "forward" type; the relevant properties of the aquifer or reservoirs are assumed to be known, as well as the initial and boundary conditions. A model then predicts the resultant flow. This is typically the approach used to map a scenario caused by lot of complex interacting partial processes or taken in sensitivity studies, which are quite useful, and can show what the most important features or processes are likely to be for a site [227 – 229]. Following the ideas of forward problems, structured or cybernetic approaches for the description of biological systems can also be mentioned. They structure the cell mass into several intracellular compounds and functional groups which are connected and regulated via an optimal criterion to each other and to the environment by fluxes of material and information. The functional groups may, in one extreme, consist of detailed reaction network considering as many as known reactions and regulatory loops [230, 231].

Mostly, however, in bioprocess engineering when microbiological and biochemical reactions are involved, the exact stoichiometry is unknown. In the engineering literature of the last 20 years a less precise mathematical model for

biotechnological processes is encountered [232, 233]. The so-called "general reactor model" – firstly introduced by Bastin and Dochain [232] – tries to unify chemical, biochemical and microbiological process using the same approach. The bioprocess, an n-dimensional system of ordinary nonlinear differential equations, is based on a simple representation of the biotechnological processes, where superfluous details are omitted. Only the dynamics of those components that play an important role in the process are considered, irrelevant byproducts or nonlimited substrates are neglected. The stoichiometry of the chemical reactions is only qualitatively taken into account by means of yield coefficient $Y_{\zeta(\cdot)/c(\cdot)}$ or stoichiometric coefficients k^*_{ij} (Eqs. 8 and 9).

$$\frac{d\varsigma_i(t)}{dt} = \sum_{j=1}^{M^*} k^*_{ij}\varphi_j\left(\varsigma_1(t), \ldots, \varsigma_N(t), T(t)\right) \tag{8}$$

$$Y_{\varsigma_j/c_i^*} = \frac{\sum_{J=1}^{M^*} \frac{d\varsigma_j}{dt}}{\frac{dc_{i^*}}{dt}} \tag{9}$$

where $c_i(\cdot)$ and $\zeta_i(\cdot)$ are concentrations of the different (bio-)chemical components, $c_i(\cdot)$ are those substances (i^*=1, ... ,N^{**}) whose reactions are calculated by the yield coefficients $Y_{\zeta(\cdot)/c(\cdot)}$, ζ_i are those components (j=1, . . ., N^*) whose turnover are determined by the dominating reaction rates ψ_j.

M^*	Number of the dominating reactions in the considered volume
$\psi_J(\cdot)$	Reaction rate of the j-th reaction
$T(\cdot)$	Temperature

In general, these coefficients do not have any mechanistic meaning in contrast to the above-mentioned approach, instead they represent formalkinetic quantities, which must be estimated, determined experimentally, or established by practical experiences. This allows the inclusion of chemical, biochemical, and microbiological processes in a unified approach. However, the reaction scheme may be inconsistent with the law of conservation of mass. Also cell-to-cell heterogeneity, e.g., due to different proliferation phases, are not considered and simplifies a segregated viewpoint to an unsegregated perspective.

The reactions rates can be often a very complex function of the operating conditions and of the state of the biosystem. In the case were ψ is proportional to the specific growth rate of the organism μ, there exist several possible models [234]. This approach is very common in literature (overviews in [235, 236]) and can be assigned – in contrast to the above-mentioned approach – to the class of inverse problems.

It is typical for *inverse problems* that in many situations the quantities that we wish to determine are different from the ones which we are able to measure. If the measured data depend, in some way, on the quantities we want, then the data at least contain some information about those quantities. Starting with the data that we have measured, the problem of trying to reconstruct the quantities that we really want to know is called an inverse problem; we measure an effect and want to determine the cause. Typical applications of inverse problems are model identification and estimation, image analysis, numerical analysis, or navigation [237, 238].

8.1.3. Dynamics of Biosystems and Real-Time Considerations

Real-time considerations play an important rule dealing with process control strategies. A notorious underestimation of the dynamic properties of microbial and cellular populations exists and results mainly from matching the duration of the respective batch cultivations to the relevant time constant of the biosystem under investigation. However, metabolic regulation of enzyme activities and fluxes often takes place on a time scale of seconds rather than days although the latter may also be true for some processes. It is therefore in the scope of promoting biotechnological research to adopt and develop appropriate experimental concepts, methodologies and equipment in order to consider all relevant time constants [239].

What is fast? What is slow? What is relevant? The last question is the most important when dealing with modeling. The relaxation time concept of Harder and Roels [240] (Fig. 28) maps typical time constants of microbial and cellular control on the level of modification of enzymes (activation, inhibition, dis-/association of subunits, covalent modification or digestion) to the range of milliseconds to seconds, on the level of regulation of gene expression (induction, repression, or derepression of transcription) to min-

Figure 28. Concept of relevant relaxation times and time constants (according to [240]). Note that the time scale is logarithmic

utes, on the level of population selection and evolution to days and larger units. Considering mainly the growth of microorganisms, typical time scales of 0.3 to 20 h are relevant. The examples discussed below will illustrate how bioengineering is facing the individual time constants.

A typical bioprocess, if operated in batch mode, extends over several hours or a few days. If operated in continuous mode, it is not reasonable to accept operating times of less than a month (see, e.g., Heijnen et al. [241]). If an organism has special physiological features such as baker's yeast, a transition from one to the other domain (e.g., from low to high dilution rates or, in other words, from purely oxidative to oxidoreductive growth) may also result in considerable changes in the time required to approach a new steady state. Axelsson et al. [242] reported a rough estimate for this case: the time constant for experiments at low dilution rates (D<DR, where DR=D at which the regulatory switch between oxidative and oxidoreductive metabolism occurs) is, as expected, in the order of the mean residence time (τ=D$-$1) however, above DR, the time constant was predicted to be at least one order of magnitude greater. In experiments specifically designed to verify this, either even greater time constants or no unique stable steady states at all were found [243].

If excess carbon and energy source is pulsed to a carbon- and energy-limited culture, the intracellular ATP concentration initially drops because of the phosphorylation sink (glucokinase and/or hexokinases). Only later, during catabolism, can the energy provided by this extra substrate be liberated in terms of new ATP. The duration of the ATP sink was predicted to be in the order of a few tens of seconds by Nielsen et al. [244]. Obviously, such rapid reactions are under kinetic control and the necessary enzyme activities are present in sufficient quantities. It is not clear, at present, whether the fluxes attain their organism typical maximal values immediately or some fine tuning of enzymatic control precedes this event. It is likely that in the latter case a regulation of (intracellular) enzyme activity, if at all necessary, takes place on the level of enzyme modification (e.g., phosphorylation) rather than on the level of de novo production (i.e., control on the transcriptional level) because the latter would require much more time [245].

The *dynamics of microbial cultures* have an important impact on the characteristics of measurement and process control. The "typical time constant" in a bioprocess is often erroneously anticipated to be equivalent to the entire duration of cultivation. However, the quantitative investigation of substrate uptake requires a time resolution of a few 100 ms, otherwise artifacts must result [246, 247]. This statement was evidenced only after a suitable technique had been established: glucose metabolism was stopped within 100 ms by spraying the cell suspension from the overpressurized bioreactor into 60 % methanol which was pre-chilled to $-40°$C.

The relevant *relaxation times* of a culture system are determined by the actual cell density and the specific conversion rate (capacity) of the culture, that is, by one or more operational and state variables (for instance feed rate, the concentrations or activities of cell mass and of effectors, if relevant) and inherent characteristic properties of the biosystem which are represented by parameters. There are metabolites with a long lifetime and other (key) metabolites with very short lifetimes, e.g., molecules representing the energy currency of cells such as ATP and other nucleotides. Rizzi et al. [248] and Theobald et al. [249] have shown that the energy charge response to a pulse challenge (ATP) of a yeast culture is a matter of a few seconds only. However, the responses can differ considerably when pulses or shifts are applied to cultures of different recent history [245, 250]. Neubauer et al. [251] found that substrate oscillations greatly affected the growth performance of *E. coli*. Short term, that is, less than 2 min, glucose excess, and starvation were investigated in a looped system of a stirred tank and a plug flow reactor. The metabolism changed within some few minutes totally from anaerobic to aerobic and vice versa. Similar observations have also been made for yeast [252].

Two other paradigms demonstrate that the band width of relaxation times is extremely broad: 1) the time required to achieve a new steady state in a chemostat culture is approximately determined by $(\mu_{\max} - \mathrm{D})^{-1}$. 2) The time required by a culture to consume a considerable fraction of small amounts of residual substrate during sampling – and thus systematically falsify the analytical results if no appropriate inactivation takes place depends, among others, on the cell density and can also be in the order of a few seconds only.

Even simple static models are very valuable for compensation of systematic errors built into automated analytical procedures. One important example is the case when sampling requires a well-known but non-negligible time. A bypass behaves as a plug flow type reactor fraction where flow dependent spatial gradients develop and where no inactivation can take place because the bulk of the bypassed aliquots are returned to the reactor. The cells continue to consume substrate while they are being transported from the exit of the reactor to the filter. The permeate recovered is representative for the filter site but not for the reactor. Knowing the transport time and some basic kinetic parameters one can easily compensate online for such errors provided that a useful estimate of the actual biomass concentration is available. Even though a bypass can be tuned to operate at a mean residence time of 5 s or less, this can be enough for a significant decrease in substrate concentration in high-density cultures. Sample buses need a minimal (dead) tune for transportation of the sample and in situ filters tend to fail in high density cultures because of rapid fouling. Hence, the problem is real and can not be ignored.

8.2. Biotechnological Measurement Systems

All measurements have the ultimate goal of creating representative information from the biosystem involved. Cellular or biochemical quantities are the primary variables in bioprocess engineering. They mainly determine the performance of the bioprocess and are therefore of special interest [253, 254]. Measurement and acquisition of information are building the fundament for all process observations as well as for the development of new bioprocesses. They represent the presupposition for process optimization and control. However, they must be available online to exploit them in a control strategy. Measurements are not only key issues in modern process development, they also open the door to a detailed process supervision and understanding, and avoid restricted views when analyzing processes just through a keyhole [255, 256].

In comparison to other disciplines such as physics, mechanical or electrical engineering, sensors useful for online monitoring of biotechnological processes are comparatively few; they are mostly available for physical and chemical quantities rather than for biological ones. The reasons are manifold, but generally biologically relevant information is much more difficult and complex to access and interpret than those for typical physical or chemical quantities [257]. Other important reason derives from restricting requirements for the sensor equipment, namely

- Sterilization procedures,
- Stability and reliability over extended periods,

– Application over an extended dynamic range,
– No interferences with the sterile barrier,
– Insensitivity to protein adsorption, surface growth,
– Resistance to degradation or enzymatic break down, and
– No disturbances from matrix compounds (interferences, matrix effect).

These aspects are in an industrial environment covered by the fact that the operation of the analyzer and its service must be as simple as possible. The aim of applying such a measurement system is to get more information but not to increase the chances of malfunctions of the whole process. Due to the complex nature of many process analyzers this requirement can only be met in some exceptional cases. Finally, material problems can arise from the constraints dictated by sterile process conditions or by biocompatibility, which often make the construction of the sensor hardware rather difficult.

8.2.1. Process Requirements Concerning Measuring Quantities

In modern bioprocess engineering there are undoubtedly only a few variables that are generally regarded as essential. Among these are several physical (i.e., temperature), less chemical (pH-value) and even less biological quantities (cell concentration). Figure 29 gives a summary of what is nowadays believed to be a minimum set of required measurements in a bioprocess. Such equipment is typical for standard production of biomaterial [258]. However, the conclusion that these variables are sufficient to characterize the microenvironment and activity of the biocomponents, of course, is more than questionable. For the consideration and compliance of the process targets, as described above, besides some environmental and operational quantities, in particular the important biochemical state variables of the biosystems must be known, namely the amounts and composition of the active *biomass*, of the *starting material,* of the *products* (and byproducts) or other metabolites. Modern bioprocess observation systems try to overcome the lack in the instrumentations, by building up functional relationships between these quantities. The approach is to substitute the direct measurement by a function based value, calculated by other measured values. But this implies thorough problem awareness and is restricted to specific boundary conditions (see Section 8.2.2).

Figure 29. Common measurement instruments and control units of bioreactors as generally accepted as routine equipment (→ measurement only, ⇆ measurement and open- or closed-loop control)

Biomaterial. The active biomaterial is of paramount importance to scientists as well as to engineers. It is an indicator for the available quantity of biocatalysts. It is definitely an important key variable, because it determines – simplifying- the rates of growth and that for biotransformation. Almost all process descriptions and optimization tools contain the quantity of biomass as the most important state variable.

The biomaterial of interest depends on the system considered: microorganism, enzymes, nucleotides, or simple protein amount and constitution. Many control strategies involve the objective of optimizing the biomaterial concentration. For automation purposes, the biomass is mostly seen as a homogeneous entity, being aware that this represents an uncertainty because segregation into different individuals is more realistic. An ideal measurement of the bioactive compound would include their activity, physiological state, morphology, or other classifications rather than just their mass. But these quantities are normally ill-defined and, in general, inaccessible to online measuring devices.

A series of sensors and methods, that can be automated and have appeared in the recent decades for the measurement of the total biomass without discrimination of any segregation (e.g., active or inactive cells). Many of them rely on optical measuring principles [259, 260], others exploit filtration characteristics [261, 262], electrical properties of suspended cells [263, 264], or thermodynamic laws [265]. One has to decide according to the specific application, which method seems to be appropriate concerning the boundary conditions, because all methods reply on indirect measuring principles, and the access of the information carrying signal differs in non general ranges. To get online information about the actual state of the biomaterial techniques based on fluorescence principle, especially the 2-D fluorescence spectroscopy, should be mentioned. It represents a noninvasive method to analyze intracellular compounds. Technically, either intra- or extracellular fluorophores (e.g., NAD^+, Riboflavin, Tyrosine, ATP) are excited by visible or ultraviolet light, and the fluorescent light emitted by the fluorophores at a longer characteristic wavelength is collected and gives information about their concentration [266 – 268].

Substrate. The presence of sufficient and appropriate starting material (substrate) is the cause of any biotransformation and represents the supposition of the product formation. One can solve the inverse problem, namely conclude that biological activities cease whenever an essential substrate is exhausted, and thus omit the measurement of the substrate, provided the progress of the bioprocess and/or product formation is known [269]. But, this is not always a proper solution because there are many more plausible, and also probable, reasons for a decrease in bioactivities than just their limitation by depletion of a substrate. One must, then, solve the direct problem, namely analyze the relevant quantities of the biological unit. From an engineering point of view this measurement should be available instantaneously in order to be able to control the desired process characteristics. In environmental biotechnology, in particular, the objective of a bioprocess can be to remove a starting material as completely as possible rather than making a valuable product. So, the starting material is identical to the process product. In some other bio- or food technological processes, the conversion of a substrate from specific state of aggregation to another is of special interest. For example, in the case of fouling of heat exchangers where dissolved proteins are transformed to a solid protein layer, the starting material changes only its state not its chemical structure. Or, considering drying or thawing where water changes its state (or is removed) which strongly influence the quality and behavior of the biomaterial involved, but no (bio-) chemical conversion takes place. The classical methods to determine these quantities are offline laboratory methods so far. This implies that samples are taken, sometimes aseptically, pre-treated, and transported to a suitable location, where storage of these samples might be necessary before analyzing manually. These steps need a lot of human and instrumental resources.

Product. The product is almost the only reason why a process should run. The main concern is in maximizing the profit, which depends directly on the volumetric productivity and/or on the purity of the resulting product. It is therefore of essential interest to know the quantities, which require measurements. What was said above about substrate determination and the application of classical methods is valid here, too.

In summary, bioprocess science needs significantly more quantitative measurements. It is insufficient to know that something happens, we need to know almost instantaneously, online and automatically why, how, and to what extent a bioprocess behaves [270].

8.2.2. Online Sensing Devices

The development of increasingly sophisticated equipments for measuring of starting material and products represents one trend to satisfy the growing demand for high-quality measurements. In contrast to engineering disciplines such as mechanical or electrical engineering, in bioprocess engineering almost no measurement performed is directly, i.e., none is obtained by immediate comparison with a reference quantity. Most measurements are achieved by means of some specific physical or chemical property of the process value, often hidden in the very complex sample matrix com-

mon to bioprocesses. This very complex matrix, which consists of the numerous substances and parameters surrounding the analyte and their mutual influences, makes the task of measuring difficult and leads to the development of more and more complicated measurement techniques [271, 272]. The surrounding equipment, i.e., for the sample pretreatment, exceeds the pure analytical core [273 – 275]. However, the greater the measuring system complexity, the more difficult it is to ensure the accuracy and the reliability of the collected data. The need for accuracy and reliability increases even more if the data of the process analyzer should be used as input for a closed-loop controller. When unreliable measurement systems are used, the system operator can only hardly decide whether an occurring variation is due to an error of the analyzer or a result from the bioprocess itself.

The final goal of the measuring unit of a bioprocess is to build up simple online instruments in order to collect all necessary information from the biosystem, which is necessary to hold the defined process targets. Therefore, the process targets should represent the selection criterion for defining the measuring equipments. The information should be available online and no manual interaction should be necessary to obtain the desired measuring results. This aspect touches the term "system observability" (see Section 8.4.1), which is strictly defined for linear systems, but eludes a definition for nonlinear systems as they are common for typical biological systems [276, 277]. It is not obvious and definable whether all system information is available und known to reach the observability in respect to the process goals or which sensors are still necessary to reach the specified process goals. The consequence is that there are normally one or more state variables (or linear combinations of them) that are hidden from the view of the observer (i.e., measurement equipment).

Concerning the information treatment there can generally be made different classifications, which are important for industrial applications. From the communications engineering point of view the information can be distinguished between *online* and *offline*. If a continuous automatic correlation between the signal from the sensor and the product or process quantity is possible an online signal is available, otherwise it is offline. A measurement is called *inline*, when a direct interaction between a product property and sensor exist, otherwise *exline*; this is more a technological characterization. Depending on the site of installation, one discriminates further between in situ, which means built-in, and ex situ, synonym for a bypass configuration or for an exit line. In the latter case, the withdrawn volumes are lost for the process. A further classification can be made by the mode of operation of the sensing device. One can discriminate between continuous and discontinuous signal generation in a predefined time step. This is a very important fact for planning and developing an appropriate process controller considering the time scales of the bioprocess. In the latter casem, one has to guarantee that the process information is available in real time.

Only online sensors are of special interest concerning the process control of biotechnological systems. Indeed there exist a couple of different, very powerful systems for the offline analysis of nearly all relevant substances. For online sensors, the situation is quite different. In situ instruments exist only for a few quantities like the measurement of temperature, pH, pressure, oxygen, carbon dioxide, density, flow rates, electric power consumption, or redox potential. They use different measuring principles and are widely introduced in industrial process engineering.

However, for the most important biological quantities in biotechnological systems especially the measurement of active or inactive biomass or the specific determination of individual biochemical substances there exists a deep lack in online instruments. In the following, principal techniques should be presented, which possess a certain online capability. See also → Biochemical Separations; → Mass Spectrometry; → Surface and Thin-Film Analysis.

Chromatographic Methods. A review of chromatographic methods is beyond the scope of this contribution. Both (high-pressure) liquid chromatography and gas chromatography have been applied in numerous cases to offline analyses of biotechnological samples, but online applications, especially for industrial processes, have only recently been reported [278 – 282]. The scope of chromatographic methods is the separation of the individual constituents of mixtures as they pass through columns filled with a

suitable stationary phases. As disadvantages the consumption of almost expensive reagents must be mentioned. The samples injected are to be pretreated in such a way, that they possess nearly no impurities, like gas bubbles or solid compartments. Any existence of those interferences disturbs the analysis in a significant manner, and manual service procedures are mostly the consequence. Furthermore the measuring time last up to 30 or 40 min; a time period which is often too large for bioprocess supervision. But also economical aspects must be taken into consideration. Chromatographic systems possess a high cost price. Furthermore, high-specialized staff must service them frequently, an aspect, which represents the major drawback for an industrial application.

Mass spectrometry. A further measurement method, in principal suitable for online applications represents mass spectrometry (MS). Mass spectrometry has been mainly applied for the online detection and quantification of gases such as p_{O_2}, p_{CO_2}, p_{N_2}, p_{H_2}, p_{CH_4}, and even H_2S, or volatile substances such as alcohols, acetoin and butandiol [283]. Generally, the detection principle allows simultaneous monitoring and, consequently, control of metabolites. The principles, sampling systems, control of the measuring device and application of MS for bioprocesses have been summarized elsewhere [284]. Of course, mass spectrometry requires very expensive equipment and needs frequent and complex service procedures. But it should be taken into account that automatic multiplexing of different sample streams is possible and, in addition, a great variety of different substances can be determined simultaneously. Thus, one has to decide, whether the high economical and applicational expense is justifiable in comparison to the advantages due to the acquisition of information.

Biosensors. The most promising technique to overcome these problems, represented in the last decade, is the use of biosensors . Biosensors consist of a sensing biological module of either catalytic (e.g., enzymes or microorganism) or affinity reaction type (antibodies, cell receptors) in intimate contact with a physical transducer (electrochemical, optic, calorimetric or acoustic sensor). The latter finally converts the (bio-) chemical into an electrical signal (overviews in [285 – 287]). In spite the fact, that principally for nearly all biochemical substances an biological recognition unit exists, biosensor applications in an industrial surrounding often concentrate only on a small group of substrates, namely glucose, ethanol, or lactate [288 – 292]. Generally, biosensors are tricky to handle and must in principle be recalibrated in the matrix where the measurement should take place every time the process conditions change. Due to the sensible biological element – an enzyme or living microorganism – they principally cannot be sterilized. They also suffer from changes in the environment, for example, changes in pH or formation or existence of aggressive chemicals such as H_2O_2 [293]. Therefore, they must be used in a suitable environment. Furthermore, the surrounding must be constant, because in general an interrelation to the endogenous matrix exists. If the process media changes significantly, the biosensor alters its behavior. A compensation of the changed matrix interferences becomes necessary. This represents one of the most decisive drawbacks in inline biosensor applications for bioprocess engineering [294 – 296]. The long-term stability under working conditions is often poor; they must be serviced for several hours per week preferentially by high-specialized staff. In this way, only limited experience could have been gained under technical process monitoring conditions. They possess only in some exceptional cases a real industrial potential.

A reasonable way around the problem represents the measuring of the biotechnological media after removing a sample from the reactor in a bypass configuration. Consequently, the sensor is not installed in situ as it would be optimal but the information could be provided online and can be fed into an automatic process control system. Depending on the analyte of interest, i.e., whether it is soluble or (in) the dispersed phase, one needs to sample either the entire culture liquid or just a supernatant. The latter can be acquired using for example a membrane module. Concerning sampling, four aspects must be taken into account.

1) The system must be opened in such a way, that no infections can enter the reaction space either during sampling or between the sampling events.

2) A representative sample must be provided. So the overall volume of the sampling chamber as well as the position of device at the bioreactor must be determined properly. Additionally, the sample taken can still continue to react on the way to the sensor. In this case the sample would not be representative for the interior of the reactor, and appropriate additional measures or modeling approaches need to be taken in order to assure representativity.
3) When native samples are applied to the analytical system, problems can arise from *matrix interferences* and *matrix effects* [297]. Therefore, the sampling device should be chosen in that way that no interaction with the matrix occur which interferes the measurement (e.g., absorption of substrate at the membrane). On the other side, the sample device should withhold all the cross-sensitivities for disturbing co-components.
4) Due to the high number of individual system components and their complex interaction (i.e., sample pretreatment and analytical part), sampling devices provoke a small reliability in regard to the required process time. Furthermore, the hardware, necessary for the whole analysis system entails high original costs. The specific adaptation to one concrete process condition implies inflexibility. It excludes the determination of other metabolites in other process media. Its adaptation is only possible by time- and money-consuming alterations.

Flow Injection Analysis. The most important technique of sampling methods in biotechnology, behind some conventional devices like membrane modules, represents the flow injection analysis (FIA), firstly introduced by Ruzicka and Hansen [298]. It can be viewed as a general solution-handling technique or sampling device combined with a sensing unit. This combination causes a high flexibility with respect to the combined analytical procedure. It can be seen as a principle where a small injected volume (10-200 μL) is introduced into a continuous unsegmented stream of carrier. The sample disperses in a well-defined concentration gradient and is transported by the carrier stream to the reaction zone and a subsequent detector module. FIA cannot generate continuous signals. But, there are several important advantages like a high sampling frequency (up to $>100\ h^{-1}$), small sample and reagent consumption, high reproducibility and nearly total versatility of the sensing methods.

Software Sensors. The most promising method to get online access to important key components of bioprocess quantities are software sensors. In general, software sensors supply the estimation of the missing measurements by using an appropriate model that relates the corresponding variable with other physical or chemical measurements that are correlated to it in any way. The fact that the model is implemented by means of a software package (hence the expression soft(ware)-sensor) denotes, that software sensors provide a software backup for unavailable sensors, as an alternative to a hardware back-up using spare sensors [299 – 302].

Generally, software sensors are typical solutions of so-called inverse problems (see Section 8.1.2). In a complex biological system, in particular, the quantities which are normally easiest to measure are the variables, not the parameters. In the case of metabolism, the usual parameters of interest are the enzymatic rate and affinity constants which are difficult to measure accurately in vitro and virtually impossible in vivo [303 – 306]. Yet to describe, understand, and simulate the system of interest we need knowledge of the parameters. In other words, one must go backwards from variables such as fluxes and metabolite concentrations, which are relatively easy to measure, to the parameters.

In other words, when using software sensors there must always be a model available that reliably relates the measured variable with the target variable or parameter of interest. Normally, measured variables are easily measurable effects that are caused and influenced by the target. It is the special objective of the software sensor to reach a maximal degree of generalization. However, this is very difficult – even impossible – to achieve or furthermore to prove this claim. Thus, the basic question is: Is the available information representative enough to generate a model for the accurate estimation of the quantity of interest, or is the desired information inaccessible by the chosen sensor collection? Consequently, the development of software sensors is often restricted to a specific application; any transfer to

other measuring problems is almost combined with considerable alterations. This does not concern only the determination of the new parameter at an identical model structure. Instead a complete new system definition can be necessary, where new input variables must be added or dispensable one can be deleted.

Spectroscopic Methods. In this context the use of spectroscopic methods [307 – 310], after optical or sonic stimulation play a dominant rule. They must be seen as multisensor systems. Their common property is the detection of absorption degrees after stimulation at various frequencies. By this, a set of information is generated, which possesses more information than the measurement at one specific frequency, the measurement at one frequency can be seen as the output of one sensor. The multivariate evaluation in an appropriate model should subsequently reveal the accurate determination of the desired quantity. In such models, normally pure data are used, the integration of knowledge from well-known fundamental equations is only very hardly to realize. The most important advantage of spectroscopic methods is their non-invasive character. The sensing device is not in direct contact with the media or the process itself, so no interference is to be expected.

The situation is even more complicated since things develop in relation to time. The estimation of the physiological state of a culture involves more than one (measurable) variable at a time and the recent history of this set of individual signal trajectories involved. Consequently, physiological state estimation requires recognition of complex patterns. Various algorithms used for this purpose to build up the (data-)model have in common that it is not always the present values alone that are evaluated, there is always the recent history of signal trajectories involved. Concerning the models, some authors define software sensors only on the basis of neural networks but a broader point of view should be adopted since software-sensor models are also obtained by using regression or correlation techniques as well as fuzzy logic or first-principle models or combinations of all of them [306, 311 – 314].

In some cases, the data describing the actual state and their recent history are compared with so-called reference patterns: these are data from historical experiments or runs which an expert has associated with a typical physiological state. A physiological state is recognized either if the actual constellation matches any one of the reference sets best – in this case, there is always an identification made – or if the match exceeds a predefined degree of certainty, e.g., 60 % – then it can happen that no identification or association is possible when the pre-selected threshold value was not reached. The direct association with reference data needs normalization (amplitude scaling) and, probably, frequency analysis in order to eliminate dependencies on (time) shifts, biases or drifts.

In other cases, the data trajectories are translated into trend qualities via shape descriptors. These combinations of trends of the trajectories of various state variables or derived variables define a certain system state; the advantage of this definition is that the association is no longer dependent on time and on the actual numerical values of variables and rates [315].

8.2.3. Further Aspects Concerning Measuring Systems

Online measurements produced with in situ sensors are difficult to validate. The usual procedure for evaluating the quality of a measurement is restricted to calibration/checking prior to and after an experimental run. A few sensors such as the p_{CO_2}- or the Cranfield-glucose sensor [316] allow removal and, therefore, recalibration of the transducer during a run. External chromatographs and FIA systems can be regularly recalibrated but the sterile interface cannot. Other sensors such as a pH or a p_{O_2} probe can be mounted via a retractable housing, which allows either sterile exchange or withdrawal for external recalibration during a run. A further possibility to gain information about the reliability of a measurement is to mount a number of identical sensors in easy-to-compare positions and to check the individual signals for equality. This opportunity has been exploited in particular at applications where a high process safety must be guarantied. It is highly desirable to have alternative principles of measurement at hand, which operate simultaneously (heterogeneous redundancy) or to introduce a self-supervision op-

tion, like pattern recognition to generally identify malfunctioning sensors [276].

Elemental balancing permits the determination of (other) metabolic rates provided that the stoichiometry is known. Carbon balances are the most useful but the carbon lost via the exhaust gas (as CO_2) and culture liquid (as HCO_3^-) must be measured. HEINZLE et al. [317] determined that the state predictions based on experiments with a small mass spectrometer are not useful due to unacceptable error propagation; for instance, a 1 % relative offset calibration error could result in a prediction error for an intracellular storage material (PHB) of >50 %. Instead, using a highly accurate and precise instrument (absolute errors <0.02 % gas composition) together with automatic, repetitive recalibration resulted, however, in reasonable estimation of substrates, PHB, and biomass. Others have also experienced these findings, e.g., [318, 319].

The undelayed evaluation of the state of a culture by using software sensors and computers, based on the quantitative analytical information provided by hardware sensors and intelligent analytical subsystems, constitutes an excellent basis for targeted process control. Experts – either human or computer – have the data and the deterministic knowledge to trace observed behavior back to the physical, chemical, and physiological roots thereby gaining a qualitative improvement of bioprocess control, a quantum leap: process control can act on the causes of effects rather than just cure symptoms. A simple standard operating procedure [320] has proven useful in this concern, namely:

- Measure everything that can be measured at the very beginning of process development
- Decide whether or not a variable is relevant
- Determine the relevant variables to be measured, controlled, and/or documented
- Collect all raw data at any time and distinguish online between variable and parameter behavior
- Organize an archive of all these data accordingly and do not discard seemingly useless data since they contribute to the treasure of experience

If it is, as some people say, correct that today's bioengineering with all its tools and methodologies is too slow and not efficient enough, then it is all the more urgent to improve the performance of the methods, tools, and equipment currently available and to invent new and better ones. In essence, techniques of instrumentation, operation, and causal analytical interpretation of measurements need massive impulses.

8.3. Cognitive Computing

*Artificial neural network*s (ANNs) are dating back to 1943, firstly reported by MCCULLOCH and PITTS [321], then fallen into oblivion, but started a tremendous comeback in engineering science with the publications of RUMELHART in 1985, who introduced – again – the backpropagation algorithm and demonstrated its potential as a learning procedure in neural networks [322, 323]. *Fuzzy Logic* has been introduced by ZADEH 1965, firstly ignored consequently by technicians because of their undeterministic and uncertain nature, but provoked a second wave of interest in the 1980s predominantly in Japan in respect to their potential in treating highly complex, nonlinear multiple input multiple output (MIMO) systems in technical applications [324]. JOHN H. HOLLAND published 1975 his classic work "Adaption in Natural and Artificial Systems"; it can be seen as the pioneer work in *evolutionary programming* [325]. Compared to other mathematical principles, these three methods are fairly new approaches and did not gain not exclusive acceptance by scientists and engineers. The three methods mentioned above can be seen as the main representatives of a class of problem-solving methods taking nature as a model, especially how it has learned to solve problems. They can be summarized to the area of cognitive computing.

It is not within scope of this contribution to explain these methods in their basic principles and functionalities. Rather, their intrinsic principles are assumed to be well known; overviews and extensive explanations can be found for fuzzy in [326 – 328], for ANN in [328 – 330] (see also → Process Control Engineering, Chap. 13) and for evolutionary programming in [331, 332]. In the following, the focus lies on two methods, on fuzzy logic system and on *ANN*, because of their high applicational potential, especially in bioprocess engineering [333, 334]. The explanations should show their potential, typical aspects and also some critical

remarks, in particular in respect to bioprocess engineering applications.

Neural networks and fuzzy theory have been underground technologies for many years. They have had far more critics than supporters for most of their brief history. However, in particular due to their application potentials in different engineering areas where classical approaches failed, their acceptance is growing steadily. Neural networks and fuzzy systems estimate functions from sample data, they map inputs to outputs. Statistical and artificial intelligence approaches also estimate functions. On the other hand, for each problem statistical approaches require knowledge how outputs functionally depend on inputs, in other words they need a mathematical model. Thus, their fundamental ideas can be more compared to typical conventional mathematical principles. Instead, neural and fuzzy systems do not require such a mathematical model. They can be seen as model-free estimators [328].

From another point of view, artificial intelligence expert systems can also be seen as model-free estimators, they map conditions to actions. However, experts do not articulate a mathematical transfer function from the condition space to the action space and the AI framework is symbolic. Symbolic processing favors a prepositional and predicate calculus approach to machine intelligence. It does not favor numerical mathematical analysis or hardware implementation. In particular, symbols do not have derivatives; only sufficiently smooth functions have derivatives. Symbolic systems may change with time, but they are not properly dynamical systems, nor systems of first-order difference or differential equations. Therefore, they are unsuitable for modeling purposes in bioprocess engineering.

A small excurse to neural (pre-) attentive processing in human intelligence should illustrate which ideal result a cognitive system provides after its learning phase. Take a look at the *Kanizsa-square illusion* (Fig. 30).

What do we see when we look at the Kanizsa square [335]. We see a square with bright interior. We see illusory boundaries, or do we? We recognize a bright square. Indeed, technically we cannot see it, because it is not there. The only things which are shown are four three-quarter circles, nothing more. The square exists only in our brain, not "out there" in physical reality on this page. Immanuel Kant called these four ink stains 1783 noumena "things in themselves". Applied to technical problems, this means that we recognize information or generalize artifacts in that way, that we see not only the input–output mapping, but the real relations or laws the data stands for. The data can be seen as facilities or indications for the perception of the underlying intrinsic information.

Figure 30. Kanizsa-square illusion

Today, many of the neural mechanisms that Kant could only guess are understood. We take for granted our high-speed, distributed, nonlinear, massively parallel pre-attentive processing. In our visual processing, we pay no attention to how we segment images, enhance contrasts, or discount background luminosity, even if they are the carrier of the real information. When we process sound, we pay no attention to how our cochleas filter out high-frequency signals even if we collect the data. We likewise ignore our real-time pre-attentive processing. We experience these pre-attentive phenomena, but we ignore them and cannot control or completely explain them. Natural selection has ensured only that we perform them, ceaselessly and fast. But what we really do, we recognize segmented image pieces and parsed speech units; we try to extract and introspect the intrinsic carried information based upon measured quantities.

Neural network studies both pre-attentive and attentive processing of stimuli. This leaves unaddressed the higher cognitive functions involved in reasoning, decision making, planning, or control. The nonlinear neurons and synapses in our brain perform these functions; they can deal with ill-posed problems or with a high degree of uncertainty. Natural selection evolved this capability in exemplary manner. Furthermore, it is the attempt of engineers to copy exactly this capability to technical problems by developing and using fuzzy logic systems or artificial neural networks.

Both methods try to imitate nature and both estimate input–output functions, in spite of totally different underlying principles. In contrast to statistical estimators, they estimate a function without a mathematical model of how outputs depend on inputs; this represents their main feature. They learn "from experience" with numerical, sometimes, linguistic sample data. Learning can be accomplished either by changing the system structure or by changing the system parameter; both principles are described for both algorithms [336 – 339]. Thus, the principle modus operandi is comparable. After the system problem is defined, the procedure can be divided into learning phase and prediction phase. The learning phase of ANN is quite obvious. Input data and corresponding output data are provided to the ANN; the system changes its structure or parameter, to minimize a predefined cost function. At first sight, the adaptive and learning character of fuzzy systems is not obvious. Indeed, there exist some techniques where the fuzzy system is built up autonomously based upon available data sets [339, 340]. On the other hand, in most heuristic applications a highly experienced technician does the "learning" step. He collects data, recognizes the intrinsic information, and formulates upon this information rules upon sets. Thus, the modeler performs the learning step and its result is introduced into the fuzzy system.

The most important features intelligent systems may show are *generalization* and *learning*. All intelligent systems should generalize. Their behavioral repertoires exceed their learned repertoire in that way, that intelligent systems associate similar responses with similar stimuli, small input changes produce small output changes. Furthermore, intelligent systems should learn or adapt. They learn new associations, new patterns, new functional dependencies. They sample flux of experiences and encode new information. They compress the sampled flux into a small but statistically representative set of prototypes or exemplars. Sample data, provided directly or transformed into linguistic rules, changes the system structure or parameters. In all cases, learning means changing. Neural networks learn patterns, functions, or probability distributions to recognize future patterns, filter future input streams of data, or solve future combinatorial optimization problems. Fuzzy systems can learn or formulate associative rules to estimate functions or control systems, either directly by means of data and an optimization add-on or guided by a highly experienced supervisor. It can be shown under some assumption that a neural net can approximate to any degree of accuracy using a fuzzy expert system and vice versa [341].

Neural and fuzzy systems ultimatively learn or estimate some unknown probability function $p(x)$. The probability density function $p(x)$ describes the distribution of vector patterns x, a few of which the neural or fuzzy system samples. When a neural or fuzzy system estimates a relation $r: X \rightarrow Y$, it in effect estimates the joint probability densities $p(x,y)$. Then the solution points $(x,r(y))$ should reside in high-probability regions of the input–output product space $X \times Y$. We do not need to learn if we know $p(x,y)$. We could proceed directly to our computational task with the techniques from numerical analysis, combinatorial optimization, calculus of variations, or other mathematical discipline. The need and the extent to learn varies inversely with the quantity of information available. *Supervised learning* uses or creates class–membership functions. It compares every input with the corresponding class D and proceeds learning based upon the difference. *Unsupervised learning* system processes each sample x but does not know that x belongs – or not – to class D. Neither supervised nor unsupervised learning systems assume knowledge of the underlying probability density function $p(x)$.

8.3.1. Fuzzy Logic Systems

Is uncertainty the same as randomness? Bayesian statistician Dennis Lindley [342] stated

that probability is the only sensible description of uncertainty and is adequate for all problems involving uncertainty. Lindley directs his challenge in large part at fuzzy theory, the theory that all things admit degrees, but admit them deterministically. Although, both expressions are used simultaneously in the same context, probability and fuzziness differ conceptually and theoretically. In this contribution some important differences are illustrated, more theoretical aspects and proves can be found elsewhere [343]. Fuzzy sets can be more compared with possibilities than probability. However, probability and fuzziness also share many similarities. Both systems describe uncertainty with numbers in the unit interval [0,1], consequently describe it numerically. Both systems combine sets and propositions associatively, commutatively, and distributively. The key distinction concerns how the systems jointly treat a set A and its opposite A^c. Classical set theory demands $A \cap A^c$, and probability theory conforms: $P(A \cap A)=0$. So $A \cap A^c$ represents a probabilistically impossible event. But fuzziness begins when $A \cap A^c=0$, hence $P(A \cap A) \neq 0$.

Fuzziness measures the degree to which an event occurs not whether it occurs. Probability describes the uncertainty of event occurrence. Whether an event occurs is "random"; to what degree it occurs is fuzzy. Consider an illustrating example. The probability this book will be published is one thing. The degree to which it will be published is another. From this book, only some special chapters may be edited or the whole entity gets public; this is typical for fuzziness. Fuzziness is a type of deterministic uncertainty; it handles with ambiguities. Unlike fuzziness, probability dissipates with increasing information. In fuzziness the uncertainty arises always form the simultaneous occurrence of two properties. More formally, does $m_A(x)$, the degree to which element x belongs to fuzzy set A, equal the probability that x belongs to A? This statement can be true or not, it depends on the problem existing, but in fact the point of views are quite different and so far hardly to compare. The following explanation should not explain the fuzzy steps in great detail, The focus lies upon two aspects. How are the sets defined and which rules can be determined. This is judged as the crucial aspects for fuzzy application in bioprocess engineering [344].

Following the introduction of fuzzy sets, Zadeh began steadily to develop the necessary inferencing mechanisms and modeling techniques to bring this concept to fruition [345]. In this period, it was recognized that fuzzy logic could aid in the development of control systems in which nonlinearities and time variance make the development of traditional control systems very difficult. In these cases, a human operator is often capable of controlling the plant, so a fuzzy controller can often be designed based on the operator's expert knowledge. Since that time, control applications based upon fuzzy logic models have been extensively investigated [346]. Fuzzy logic systems are similar to expert systems in their use of linguistic relationship, but the substantial difference is that the outputs are in general continuous by variation of the inputs [347]. It is exactly this property which causes the high interest in mathematical modeling, and hence in engineering science.

Mapping with fuzzy logic is analogous to classical modeling. The maps have variables which influence system behavior and relationships among the variables which describe the system. In classical models, variables have real number values, the relationships are defined in terms of mathematical functions. In fuzzy logic however, the values of variables are expressed by linguistic terms such as "large, medium, and small", the relationships are defined in terms of "if-then" rules. By using defuzzification techniques, exact numerical outputs are calculated from fuzzy subsets.

A fuzzy subset A is defined by a membership function $m_A(x_i)$, where x_i is the domain, of the variable on which A is defined.

$$m_A(x_i) \in [0,1] \, \forall \, x_i \in A \tag{10}$$

The value of $m_A(x_i)$ for each x determines the degree to which each element in the domain belongs to A. Although both classical and fuzzy subsets are defined by membership functions, the degree to which an element belongs to a classical subset is limited to being either zero or one. This means that $m(x)$ may only be a step function. In fuzzy logic, the degree to which an element belongs to a subset may be any value in the interval [0, 1]. Since $m_A(x_i)$ may be defined by any function, it is easy to see that a classical subset is a special case of a fuzzy subset [348]. The fuzzification process transforms exact values x

of fuzzy variable v_j to $m_{Ai}(x_i)$ for all subsets A_i, which are defined for the variable v_j. More rigorous definitions of membership functions may be found elsewhere [327, 349].

One technique for determining the shape of membership functions is seeking knowledge of the system from experts then constructing membership functions that represent expert opinion. Observations of many experts should be preferred. Based upon this observations, membership functions can be constructed using statistical methods accompanied by using the analysis of preferences [350, 351]. Many researchers have investigated more "rational" techniques for determining membership functions. One of these approaches represents one variant of *fuzzy clustering* [352, 353]. It requires a set of input and/or output data from the system to be collected. Patterns of data are found within the input or output space such that the variance within the sets is minimized and the variance between sets is maximized. The prototype, or center point, of a cluster X is determined and a distance metric is used to determine the degree of membership that a value has to X. Another technique for determining membership functions involves *neural networks*. Neural networks are networks of simple processors connected by adjustable weighting factors [328]. The weights are adjusted by using a backpropagation or other known algorithm to minimize the difference between the predicted output and the measured output. The parameters of membership functions can be "learned" by a neural net from a set of input–output data [354, 355]. Genetic algorithms have also been used to determine the optimal shape for membership functions [356, 357].

For fuzzy subsets to be useful in "modeling", there must be a way to define relationships between them. This is accomplished by means of their membership functions $m_{Ai}(x)$ with logical operators and inferences, to extract ambiguities. There are three basic operators in fuzzy logic, (1) OR, (2) AND, and (3) NOT, which link two or more membership functions $m_{Ai}(x)$ of different variables. The activation level of each rule is normally equal to that of the premise (activation). All rules are evaluated. If some sets of an output variable are activated more than once, an aggregation method must be chosen to determine the final activity. After defining the interferencing method, the output fuzzy sets are defuzzified to get a precise value, for further explanation see [327, 349].

Expert knowledge is the most common technique for determining rules. The expert is asked to summarize the knowledge about the system in the form of cause and effect relationships. From these the rules are formulated. When no experts are available or a more analytical approach is desired, other techniques of system identification must be used. One approach is to apply a set of *metarules* to adaptively acquire information about the system. Linguistic self-organizing controllers issue control actions and observe the environment [358]. The metarules evaluate the performance of the control actions from the effect of the control actions on the environment. The metarules then determine whether the control actions should be modified and perform the modification, if necessary. This technique has been applied especially to robotics applications [359]. Fuzzy classifier systems are another way to discover rules. Fuzzy classifier systems are generalizations of genetic classifier systems. A genetic classifier system uses some of the ideas from genetic algorithms to develop expert systems [360, 361]. Standard genetic algorithms have also been used to discover rules [362]. Sugeno and Yasukawa use the second variant of fuzzy clustering [fuzzy clustering methods can also be used to determine the membership functions (see above). Both approaches are addressed by the term "fuzzy clustering"] on data in the output space to determine fuzzy rules [363]. The clusters in the output space are used to induce clusters in the input space. Then, input space clusters are projected onto the axes to find the fuzzy subsets for the input variables. Since the input clusters are induced from the output clusters, rules can be constructed between the input subsets and the output subsets. Yoshinori et al. (1996) discuss another method of fuzzy model construction based upon clustering techniques [364]. This method produces a relational as opposed to a functional model, and consists of a series of local, linear models to approximate a global nonlinear one. Recently; neural networks have become an active field of interest and have been used to learn rules as well as membership functions [365, 366]. However, all methods, which automatically generate rules, have deficiencies in their interpreting ability. They are generated to fit available data best and it is not

obvious that the rules express reasoning relations. This can be seen as a strong disadvantage compared to the generation of rules by means of expert knowledge.

The application area of fuzzy systems is widespread and should only be presented here for applications in bioprocess engineering. The fermentation industry was one of the first to recognize the potential of fuzzy logic for biological processes [367, 368]. Konstantinov and Yoshida developed a fuzzy logic system for identifying physiological states in fermentation processes and used it to control distributed an *E. coli* fermentation [369]. Meanwhile the range of applications has enlarged tremendously. In principle, they can be divided in two fields. The first one are those where the knowledge bases is constructed such that it is based upon existing (qualitative) information, mainly from high-specialist staff. This represents the area of fuzzy modeling [370, 371], fuzzy controller [372, 373], or estimator for biosystem states or process faults [374, 375]. One of the intrinsic characteristics is that significant knowledge engineering effort is required for setting up a complete and consistent rule base. The other domain of fuzzy logic is relational model-based systems where the linguistic information is extracted from available data to build a system model. This second approach is also directed to the field of bioinformatics or experimental design [376, 377]. This approach does not need any preinformation about the intrinsic relation, however a knowledge base can arise which is hardly to evaluate or interpret. Additionally, no information can be given about the generality of the established rules. At all accounts, when a data driven construction is used, a subsequent mathematical or manual evaluation, especially of the rule bases, is necessary after the automatic construction of the fuzzy system. For the process industry, expert-knowledge-based approaches possess more interests because they follow a concrete process target. The second one can be seen as a special form of knowledge discovery which enables to accomplish some linguistic evaluation based upon data, if no expert knowledge exists. In some exceptional cases, these clustering techniques are exploited for control purposes [378]. An aggregation of both principles is also fruitful in the case where the existing information is too little to build up a representative "model". In this case, a data driven approach can help to complete the fuzzy structure.

8.3.2. Artificial Neural Networks (ANN)

Artificial neural networks are designed to mimic the actions of neurons in the human brain. For detailed information, see [328 – 330]. They represent massive collections of interconnected neurons (nodes), which individually perform a relative simple signal processing; they are interconnected via synaptic links. Like brains, neural networks recognize patterns or relations between inputs and outputs we cannot even define. They can be seen as pure function approximators whose abilities depend on the behavior of the individual nodes, the structure of the network, the learning procedure used, and on a very strong degree of the quantity of representative data. Not the total amount of data is crucial but the information content with small degree of redundancy. Almost the whole quantity space of the input and output values should be spanned by the database. Recently, e.g., Cybenko [379] and Hornik et al. [380], have proved that any continuous function can be approximated to an arbitrary degree of exactness on a compact set by a feedforward neural network comprising two or more hidden layers and a continuous nonlinear activation function, providing appropriate data.

Working with neural networks always consists of two phases, a *training* and a *prediction* phase. In the first one, the variable parameters $\vec{p}\ (t)$ of the net are changed in that way, the ANN fits best to the trainings database. In most cases, $\vec{p}\ (t)$ represents weight parameters of the intrinsic functions, e.g., the weight how the output of a neuron contributes to the activation of a subsequent node. On the other hand, there exist also some nets where the structure of the net (nodes and their synapses) can be seen as their parameters which are changed during learning. The indicator for changing $\vec{p}\ (t)$ represents a formulated performance index *J*. Based upon the absolute value *J*, the parameters are changed in order to minimize *J*.

$$\min\left(J\left(\vec{p}\right)\right) = \| \frac{\Delta J}{\Delta p_1}, \frac{\Delta J}{\Delta p_2}, \cdots, \frac{\Delta J}{\Delta p_n} \| \tag{11}$$

where p_i is a parameter *i* with $i = 1 \ldots n$ parameters in the ANN.

The definition of J depends on a couple of different aspects, but in most cases the Euclidian distance between the desired target and the calculated output integrated over all training data sets is used. Performing learning should result in the global optima concerning the specified problem. However, most training procedures are local methods, requiring a gradient calculation. And obviously, any algorithm that relentlessly crawls downward must have a very lucky starting position if it is to settle into the lowest local minimum. Avoiding false minima requires two separate procedures. First, we must elute in the initializing phase starting in their vicinity. If we settle into the neighborhood of a broad minimum, it will be very hard to escape later. Second, we require a procedure for determining whether or not we are in a local minimum, and escaping if we are. This procedure will be constructive in that we were in a local minimum. Otherwise, we assume that we have found the global optimum. In the second phase, the prediction phase, the net is conditioned to treat new input patterns, hopefully gaining the correct corresponding output values.

The nodes are connected in that way that the output of one node represents one input of the adjacent node. A node is stimulated by one or more inputs $\vec{x}\,(t)$ and it generates one output, a scalar $y(t)$ that is sent to other neurons. The output $y(t)$ is dependent on the weighted activities of each input, on the nature all inputs are transformed within the node and the parameters constellation $\vec{p}\,(t)$ in each neuron. The actual relationship between the inputs and outputs can be enormously complex, depending on the chosen of entry $E(\cdot)$, aggregation $S(\cdot)$, activation $A(\cdot)$ and output function $O(\cdot)$:

$$y\,(t) = O\,(A(\,S\,(E(\,\vec{x}\,(t)\,,\,\vec{p}\,)))) \tag{12}$$

Thus, the resulting behavior of individual neurons can be modeled by a simple weighted sum of inputs, a complex collection of interrelated or subsequent set of (differential) equations, or anything in between. There can be significant time delays in the steady-state output value after stepwise input stimuli. Neurons do not always respond in the same way to the same inputs. Even random events can be considered in the operation of neurons. Luckily, a large body of research indicates that simple models, which account for only the most basic neural processes, can provide excellent solutions to practical problems. The human brain contains roughly 10^{11} neurons. As many as 10^4 synaptic junctions may abut onto single neuron. That gives roughly 10^{15} synapses in the human brain [381]. Consequently, the brain represents an asynchronous, nonlinear, massively parallel, feedback dynamical system of nearly "cosmological" proportions.

The ability of ANN to emulate complex dynamical systems stems from the *interconnectivity of neurons*. In general an ANN has n neurons distributed in an input, an hidden, and an output section. Connections between neurons can be organized in layers such that information flows in one direction only, or it can circulate throughout the network in cyclic patterns. All neurons can be updated simultaneously or time delays can be introduced. All responses can be strictly deterministic, or random behavior can be allowed; the variations are nearly endless and should not be described in detail. Mathematically they can be formulated in the following vector equation.

$$\vec{y}\,(t) = \vec{h}\,(\vec{o}\,(\,\vec{z}\,(t)\,,\,\vec{x}\,(t)\,,\,\vec{p}\,)) \tag{13}$$

where

$\vec{y}\,(t)$	Vector of y_i with $i = 1 \ldots n_i$ outputs of the ANN
$\vec{x}\,(t)$	Vector of x_j with $j = 0 \ldots n_j$ inputs of the ANN
$\vec{p}$	Vector of pm with $m = 0 \ldots n_m$ variable trainable parameters of the ANN
$\vec{z}\,(t)$	Vector of z_j with $n = 0 \ldots n_n$ for all outputs of all individual nodes
$\vec{o}\,(t)$	Vector function of function o_m with $m = 0 \ldots n_m$ for the calculation of the individual contribution to the output y_i
$\vec{h}\,(t)$	Vector function of function h_i with $i = 0 \ldots n_i$ for the calculations of the real outputs of the ANN

There also exist some criteria to decide whether a structure is appropriate for a good modeling approach. Always, a compromise must be made between the desire to have a simple model with fewer parameters and more accurate predictions at the cost of a large number of parameters. The *Akaike's information criterion* (AIC) uses the number of data points, the overall error, and the number of parameters to determine an index, which can be analyzed to fix the optimal quantity of free parameters [382]. Another concept that may be of interest is the

use of a periodiograms, which gives an indication regarding the frequency content of the input signals, typical frequency can be characterized, which fixes the optimum degree of freedom [383]. Another way is the determination of principal components before fixing the structure of the net, thus, incorrect or redundant information can be rejected before entering in the learning phase [384]. However, care must be taken in reducing system complexity or rejecting data sets, because they can be meaningful and represent the behavior of the biological system even though, this may not be obvious from the data set.

When considering a particular application, it is to decide what type of network should be used. Principally, ANN structures are classified as either global or local. Both possess specific properties and hence applicational preferences. Global networks are the most popular und important ones. Among them, different types exist: feedforward backpropagation neural networks (FBNN); recurrent neural networks (RNNs), or cascade correlation networks (CCNs). Unlike the FBNN, RNNs are more general in the sense that connections are allowed both ways between a pair of neurons and even from a neuron back to itself on any way. The RNN allows the dynamics of the network to be considered intrinsically. In contrast, in FBNN for mapping a dynamic behavior the input variables must be supplemented by their corresponding deviations or time series. However, the number of weights (for a fully recurrent network) to be determined may easily become quite large. Therefore structural optimizers are recommended, e.g., the cascade correlation, where connections and nodes are added as required, [385]. Local networks, such as the radial basis function network (RBFN) process data in discrete areas not continuously over the whole space of the data. They are particularly suitable for applications in online control and optimization [386]. In the RBFN, it is necessary to locate centers among the input/output pairs such that the sum of the squares of the distance from the center to the training data set is minimized. These centers are equivalent in concept to the weights in the FBNN. However, the RBFN may fail in predicting values if the prediction space does not contain any center. This must be seen as a crucial disadvantage, especially for online applications. So, global networks should be preferred if high uncertainty within the data exists.

The "explosion" of ANN applications in nearly all areas of process engineering can be attributed to the following reasons:

- The tremendous hardware advances in digital technology over the past decade have enabled simulations of neural nets to be made both economically and with relative ease hand speed.
- Applications of neural networks for sensor pattern classification have been found to be superior to the traditional algorithmic techniques or the expert system approaches.
- Neural networks offer the promise of being able to extract information from a plant in an efficient manner with normal availability of data, especially if severe or unknown nonlinearities and time invariances, typically for biosystems, exists.
- Some practitioners claim that neural networks may be easier to use and apply in the real process plant, with difficult to handle nonlinearities, as compared with the modeling approach, which can be subject to various modeling errors.
- Finally, the versatility in structure and application of neural networks enables them to be utilized in the middle ground between conventional model-based approaches and black-box approaches for solving many classes of problems. These hybrid-type approaches have been another factor, which has further attracted their use in chemical process systems recently.

The applications utilizing neural network based strategies in bioprocess engineering are wide ranging. A detailed description of all application is outside the scope of this contribution. Neural networks can be used for *classification*, to specify typical classes in the sets of the data base. Any task that can be done by traditional classification analysis can be accomplished at least as well and almost always much better by networks. Very important applications in bioprocess engineering are the multivariate exploitation of sensor arrays [387, 388] or the fault diagnosis [218, 389]. An ANN can be trained for *pattern recognition*. These patterns can be a intervals of time, cultivation states, fermentation series, images et cetera. If a version

of one of these patterns, corrupted by noise, is presented to a properly trained network, the network can provide the original pattern on which it was trained [390, 391]. A very common problem and the most popular application field of ANN is that of *modeling, identification*, or *estimating* the value or the state of a variable, given historic values of itself and other variables; e.g., they were used to estimate the state of microbiological cultures [392], the concentration of unmeasurable mostly intracellular biological key components [393 – 395], or for the identification of bioprocesses [396, 397]. ANNs can also replace or act as *process controllers*. The applications utilizing these neural-network-based strategies are wide ranging and vary from linear time invariant to highly nonlinear time variant systems [398, 399]. Typical advanced representatives are the model-predictive control, the inverse model-based and the adaptive control techniques. These methods have all in common, that the ANN reacts as a process controller, modified or expanded in some way by a reference model or by an online training unit.

8.4. Modeling Aspects of Biological Systems

By definition, biochemical engineers are concerned with biochemical systems, with reactions and artifacts of biochemical substances like proteins or with systems employing growing cells. Even the simplest living cell is a system of such a forbidding complexity that any forward mathematical description of it is – in most cases – an extremely modest approximation. This situation prompts for bioprocess modeling the question from a formal logical viewpoint: "What kind of relation ship should exist between the underlying physical system and its mathematical description and which approaches should be exploited?".

Contemplation of this question leads, in one direction, into the labyrinths of philosophy science. Guidance into this territory from the learning guide Rutherford Aris led to John Casti's two-volume treatise "Reality Rules", which explores the general definitions of a mathematical model as well as numerous specific examples of models in different contexts [400, 401]. Gratefully for engineers, who are (or should be) engaged in discovery and development of useful modeling technology, Casti asserts an inextricable coupling between a model and its intended application: "Basically, the point of making models is to be able to bring a measure of order or probable system performance to our experience and observations, as well as to make specific predictions about certain aspects of the world by experience". Therefore, mathematical modeling does not make sense without formulating before making the model what is its use and what problem it is intended to help to solve. Thus, a definition of a model can be given as follows: *A model is an image of a real system that shows analogues behavior in the important properties, and that allows within a limited region in respect to the intended purposes a description of the behavior of the original systems*.

The emphasis represents the word *important*. A model should be always as simple as possible; the degree of simplicity depends only on the model purpose and on the modeler skills. Modeling the same real system with a different focus, the significant properties are mostly quite different. Single parameters can represent in one case the most specifying quantities and in the other case they are completely unimportant. The focus and the intention of the model determine not only the parameter, but also the proceeding in the formulation of the relations. The modeler must identify the important variables (inputs, outputs, states) and their separate effects, which in practice may have a very highly interactive combined effect on the overall process. This is only possible if the modeler hat a profound technological knowledge. Once the model is established, it can be used, with reasonable confidence, to predict performances under differing process conditions. But this is only allowed under specific boundary conditions, under those which were used for the set-up. If you leave them, the describing ability gets lost. Any extrapolation should be seen as critical.

8.4.1. Steps in Creating a Model

Model building is always a combination of theoretical studies and practical experiments in a very iterative sequence (Table 15). The described sequence should be observed in order

to get proper problem awareness and to minimize the efforts to reach the main targets. The objective of a scientific investigation is to improve understanding of a system by testing a hypothesis about that system. The formulation of the hypothesis is the most important action in the modeling process. In a scientific process, a problem or question is posed and stated as a hypothesis or theoretical statement of the problem.

Table 15. Step sequences for model building in bioreaction engineering. The steps must be seen as a loop whose termination is determined by the defined cost function

Step	*Action*
1	Proper definition of the problem (hypothesis), the goals, and the objectives of the study, fixing of presuppositions, boundary conditions and constraints, defining the evaluation and error criteria
2	Analysis of the system, determination of the structural elements, description of the key elements (variables, processes)
3	Running typical representative experiments, exploiting the parameter space of the control variables (experimental design)
4	Establishing the type of model by use of balances, physical–chemical–biological laws, available data, empirical equations, uncertainty treatment, problem formulation in mathematical or linguistic terms
5	Simplifying assumption (e.g. about mixing, process structure and dynamics, metabolism, kinetics, neglecting aspects)
6	Choice and definition of the important process variables: input and output variables, states, and parameters for the model
7	Simulation of the model, parameter identification, sensitivity analysis, determination of estimation properties
8	Evaluation of the model by using test data considering the evaluation criteria from step 1, if necessary starting again with step 1

For complex biological systems, however, the hypothesis may need to be translated into a mathematical tractable building and the model predictions are compared to the observed data as a basis for rejecting or accepting a hypothesis. This step also includes the definitions of the goals and the objectives. The purpose of the model usually dictates the form and the detail as well as the data that are required to develop and test it. Typical goals can be the identification of typical parameters or simulations, to predict responses to a perturbation. If the purpose is to get a general idea on how the system would behave under a new condition, the accuracy may not be important, however, if the purpose is to determine an "optimal" process trajectory, the model accuracy may be critical. Finally, the purpose may be to derive the mechanistic principles underlying the system behavior. So, it is useful to obtain as much data from the system as possible. It can be necessary to examine all different portions of the curves individually. Even, small deviations can hold large insight into the intrinsic physico-chemical effects of the biosystem.

In all real cases of *system modeling*, also boundary conditions or system constraints must be fulfilled. This requirement addresses two different aspects. The first one considers the fact that the created model is only valid inside typical boundary limits of the system variables and inside formulated constraints in respect to realized assumptions. The second one indicates that building up a model in bioprocess engineering is always accompanied with an identification step for optimizing the parameters. But the parameters are reasonable only within some limits, though they fulfill the mathematical optimal criteria. Otherwise, they can loose any physicochemical meaning or interpretational ability. Having more than one parameter to determine can lead, depending on the complexity of the system under consideration, to ambiguities. In this case, although available knowledge, e.g., in form of experimental data is represented well, the meaning of the parameters is outside of any interpretation scope. The extrapolation ability gets lost.

To accomplish a mathematical treatment of the model in order to reach the predefined goals, an evaluation criteria must be formulated. This can be seen as the mathematical description to the formulation of the modeling purpose and is realized by formulating a scalar performance index. Its quantity gives information about the model quality. In bioprocess engineering, it is normally calculated from the results obtained by the model compared with those of the corresponding experimental data.

There are two common approaches to fit models to data, the *least-square* approach where parameter are adjusted to minimize the sum (over all target values and existing data sets) of squares of the residuals between the calculated and experimental data and the *maximum-likelihood* approach, which maximizes the probability of the assumed parameterized probability density function [234]. Also, the above mentioned boundary conditions and system constraints must be considered in the performance

index. This aspect is from the logical point of view strictly necessary, but invokes in some cases crucial mathematical problems [402].

The system under study may consist of a single biomolecule, a cell, or a whole plant. Biological systems are normally open systems. They have inputs and losses, although they may also be reduced to closed systems as in vitro studies. Once the system to be studied is defined, the inputs and outputs are identified. Additionally, its processes, subsystems, and key compounds characterize the system. Processes are movements or changes in the system (e.g., absorption, metabolism, transport, chemical reactions), subsystems are components of the whole system (e.g., cells by considering the fermenter as the system), and compounds/states are the quantities under consideration (e.g., metabolites).

Almost all modeling approaches in bioprocess engineering involve an identification step of unknown parameters in the model by experimental data. The aim of the experiment is to obtain data to confirm or reject a hypothesis. It is essential to decide from which environmental and operating conditions measurable quantities should be gained, and to which precision and in which measuring range. The physical, chemical, and biological ones should be wide ranging, and should also include the quality of the whole environment and pre-cultures or pre-states. All measurable bioprocess data must be treated initially as variables. Afterwards, it could be decided, whether they remain constant or not. Automated measurement and control of bioprocesses, presently an art but – hopefully – routine in the near future, generates a tremendous amount of data. This requires judgment of the importance of these data for documentation to reduce data effectively without loss of valuable information. Experts – either human or computer – have the data and the deterministic knowledge to trace observed behavior back to the physical, chemical, and physiological roots.

Once the biosystem is structured and experiments are done, the model should be fixed. There exist different approaches to find the best appropriate model type for the underlying problem (see below). In principle, the model should represent the theories or hypothesis about how the system works. Normally, there exist different structures and parameter constellations which will fit a particular set of data. The crucial task for the modeler is to decide which one should be accomplished from the viewpoint of deep understanding of the biosystem. It is important and in most cases very effective that new approaches are built up upon information of earlier studies gained from literature. Differences between the models should be evaluated to choose the model most acceptable with current and new biological knowledge. Since the problem of parameter identification and model verification increases rapidly with model complexity, one should begin with as far as possible simplified assumptions and withdraw them step by step, if the model quality is judged to be not sufficient. In this way, a most simple initial model grows step by step in complexity and accuracy, without becoming too complicated. Modeling includes not only the selection of correct model structure, but also the determination of the undefined system parameters.

To give a final statement about the quality of model, its robustness has to be evaluated. This concerns *sensitivity*, *identifiability*, and *stability* aspects. Sensitivity refers to the relative influence of individual parameters on the solution. Identifiability refers to the uniqueness of the model and of its parameters. They should be determined in that way that a data-fitting process should return the same estimates of parameters more or less independently of the starting points for estimation and noise in the data. Stability is the behavior of a system with respect to a perturbation. Since nearly all real biological processes are time-variant and highly nonlinear in nature, the powerful collection of methods concerning the aspects of controllability, stability, and operability of linear systems cannot be applied [403].

Sensitivity analysis is one of the most important tools to optimized models. It refers to calculations and analyses performed to describe the relative dependency of the model parameters. Its analysis can be used for model validation as well as for fixing variables to constant values in order to decrease the degree of freedom. The sensitivities are also very important for interpretation purposes, e.g., to detect more or less important partial processes or quantities of the biosystem. From a practical perspective, it represents calculations which reveal the impact of assumptions made in conjunction with model development. A distinction can be made between point sensi-

tivity, relative sensitivity, and overall sensitivity. Considering the model

$$\vec{y}\ (t) = \vec{y}\ (t,\ \vec{p})) \tag{14}$$

with t representing the process time and $\vec{p}$ the parameter to identify; $\vec{y}\ (t)$ are the measurable output variables. The relationship between the state variables and the point sensitivity can be show using the first two terms in the Taylor expansion.

$$\vec{y}\ (t) = \vec{y}\ (t, \vec{p}_0) + G^T \partial\ \vec{p}\ + K \tag{15}$$

where G is the partial derivative matrix of $\vec{y}\ (t)$ with respect to $\vec{p}\ (t)$. An element of G is defined as the point sensitivity of y_i with respect to p_j. An alternative scale-free sensitivity is the relative sensitivity S_{ij}

$$S_{ij} = \frac{p_i}{y_i} \frac{\partial y_i}{\partial p_i} \tag{16}$$

To represent the overall sensitivity of a state variable as opposed to point sensitivity to parameter p_i over some time interval, S_{ij}^G can be defined

$$S_{ij}^G = \frac{1}{T_2 - T_1} \int_{T_1}^{T_2} \frac{\partial y_i}{\partial p_j} dt \tag{17}$$

As applied to modeling, *identifiability* is a mathematical concept, which attempts to steer model development largely on the basis of an analysis reflecting whether features of a model for a presumed system can be extracted from a proposed experiment. Selecting a standardized method for an experiment directed for elucidating a model and its features involves selecting time points for observations, observation sites, sites for tracer input, as well as forms of tracer application. In bioprocess engineering, it is seldom possible to sample all units, and the number of units to which tracer can be applied is limited. Each choice we make here stands for a chance of mitigating against identifying aspects of the model, even in an error-free situation. If the lack of identifiability makes it impossible to estimate unique parameters or test relevant hypothesis, we should like to know this before conducting the experiment or interpreting the modeling results. If the experiment is adequate to identify the model, we are still left with the estimation problem, that of resolving the parameters amidst noisy data and to reach the observability. Consider the following general representation of a time-variant nonlinear system:

$$\vec{z}\ (t) = T^* \left(\vec{x} \left(t \right), \vec{y}\ (t), \vec{p} \right) \quad \text{with} \quad \vec{z}^0 = \vec{z}\ (t = t_0) \tag{18}$$

A system is defined as observable at the time t_0, if, admitting an arbitrary initial state $\overleftarrow{z}^0$, a finite point of time $t_1 > t_0$ exist, so that assuming known input $\vec{x}\ (t)$ and output $\vec{y}\ (t)$ trajectories the state $\vec{z}\ (t)$ can uniquely be determined in a time interval $t_0 < t < t_1$. In contrast to linear systems, this problem involving time-variant nonlinear equations as they arise in bioprocess engineering results in nonlinear algebraic equations for the solution of which similar powerful methods do not exist. Consequently, several assumptions and individual specifications and transformations have to be made to make the problem mathematically tractable with reasonable effort [404].

8.4.2. Reasons for Making a Model

There is a zoo of mathematical models in the biochemical engineering and mathematical biology literature. Many of these appear to naive as well as to sophisticated reader to have little more purpose than calculating numbers and writing scientific papers which conform reasonably to experimental data. This is, in itself, not a distinguished endeavor; it is not particularly difficult, and it teaches little. One reason that mathematical biology receives so little respect from biological scientists – and is generally not recognized as a credible research tool in biological science and a biotechnological discovery – is that it represents the failure to communicate clearly and persuasively the reasons and the motivation for constructing a model. Sometimes the modeler himself has not clearly asked this question while doing the work, sometimes biochemical scientists make one experiment after the other, not reflecting which mathematical approach exists to enhance the evaluation or interpretation of the experiments. However, modeling as a typical domain of engineering gets increasing interest in the study of biological systems. The challenge of

modeling biological systems is not to determine an arbitrary function to fit the data but to use the modeling process to understand the system.

Modeling can be used to determine the *structure of a system* where structure refers to the relationships between various parts or processes of a system. A model can be used to determine the type of relationship as well as the sequence of events that occur between the various substances of interest. In some systems, this information may be known, whereas in others the structure can only be inferred from the data. Modeling improves understanding, and it is through understanding that progress is made. In formulating a mathematical model, the modeler is forced to consider the complex cause-and-effect sequences of the process in detail, together with all the complex inter-relationships that may be involved in the process. The comparison of a model prediction with actual behavior usually leads also to an increased understanding of the process, simply by having to consider the ways in which the model might be in error. The results of a simulation can also often suggest reasons as to why certain observed and apparently inexplicable phenomena occur in practice.

Models can be used to determine parameters of interest, such as pool sizes clearance rates or transport rates. If the purpose is to accurately determine a particular parameter, it is important that the model can be uniquely determined. However, the model must also be consistent with known biological information. A model may be well-determined but incorrect.

The purpose of the model may be to determine the *interaction of parts of a system*. Models can integrate information on a number of subsystems into an integrated form to represent the process under consideration in the whole system. Because of the interactions, dependencies, and feedback of the processes, large complex systems can only be understood by using modeling. An example could be to link metabolism in one tissue with metabolism in another, or to link metabolism of a nutrient in one form with the metabolite in a second form. Large systems and systems with dynamic properties can only be understood with the use of models. Because many processes in large systems occur simultaneously and dynamic systems are accompanied by complex interactions between processes, it is unlikely that responses to perturbations could be predicted based solely on intuition and experience without a model.

Models can be used to simulate *inputs into a system* at various sites and to simulate short-term as well as long-term responses. Experiments can be simulated rapidly using a model to predict likely scenarios before undertaking expensive experimental data collection. While models will never replace experiments, they can be used to avoid experiments where insufficient or inappropriate data will be collected for testing a certain hypothesis. Models may be used predictive for design and control. Once the model has been established, it should be capable of predicting performance under differing sets of process conditions. Thus, mathematical models can be used for the design of relatively sophisticated control and optimization algorithms, and the model, itself, can often form an integral part of the control algorithm. Optimization usually involves considering the influence of two or more variables, often one directly related to profits and one related to costs. For example, the objective might be to run a reactor to produce a product at a maximum rate, while leaving a minimum amount of unreacted substrate.

An important use for models is to identify *sites of change* in a system when studied under different conditions. In some cases, the altered condition may result in large changes in the kinetic curves and several pathways or it may result in a subtle change in the data caused by a large change in only one parameter. A model helps to identify which parameters change between the conditions and the degree of change. The conditions may be an untreated versus treated state, a healthy subject versus a diseased subject, or a normal versus high intake of a nutrient.

Models form valuable tools for teaching the process of *scientific inquiry* and for challenging students to think creatively and quantitatively about a system. Models can be used to demonstrate properties of a system, teach principles (such as feed-back loops, saturation kinetics etc.), test theories, and design studies. With the increased speed and convenience of computers, the availability of modeling software and the access to it, the researchers who are developing and publishing models, need to be cognizant of this. They need to make their models understandable

and accessible to the biological community at large as well as to students.

Models help in *experimental design*. It is important that experiments be designed in such a way that the model can be properly tested. Often, the model itself will suggest the need for data for certain parameters, which might otherwise be neglected, and hence the need for a particular type of experiment to provide the required data. Conversely, sensitivity tests on the model may indicate that certain parameters may have a negligible effect, and hence these effects can be neglected both from the model and from the experimental program.

8.4.3. Different Types and Basic Approaches for Building a Model

Incomplete knowledge of the dominant biological pathways as well as low availability of sensor information about the current physiological state is the characteristics of biochemical process modeling. From system analysis, as already described above, the definitions of the describing variables (e.g., inputs, outputs, or states) can be given.

In principle, there can be postulated that these variables are intrinsically interconnected by means of a set of – indeed real existing – differential equations, as it is already described in previous chapters. But even being aware that these relations may exist in principal, for mathematical treatment they can only be specified in their structure and intercorrelation as well as in their parameter constellation in some exceptional cases with a high degree of accuracy. Thus, when dealing with modeling of real biological systems, uncertainty in various aspects can never be avoided [405]. In bioprocess engineering, uncertainty is an inseparable companion of any modeling approach.

Uncertainties in engineering systems can be mainly attributed to *ambiguity* and *vagueness* in defining the architecture, parameters, and governing prediction models for the systems. The ambiguity component is generally due to noncognitive sources. These sources include 1) physical randomness; 2) statistical uncertainty due to the use of sampled information to estimate the characteristics of these parameters; 3) lack of knowledge; and 4) modeling uncertainty which is due to simplifying assumptions in analytical and prediction models, simplified methods, and idealized representations of real performances.

The *vagueness*-related uncertainty is due to cognitive sources that include 1) the definition of certain parameters, e.g., structural performance (failure or survival), quality, deterioration, skill, and experience of construction workers and engineers, environmental impact of projects, conditions of existing structures; 2) other human factors; and 3) defining the interrelationships among the parameters of the problems, especially for complex systems. Other sources of uncertainty can include conflict in information and human and organizational errors [406].

Once the systems are defined, the relations between the outputs and states based upon the inputs and states have to be formulated to perform simulations. Today we have many types of models, which can be categorized in various ways such as deterministic versus nondeterministic, logical (linguistic) versus mathematical-equations-based or data- versus knowledge-driven. *Physical models* can be the realization of the original system in a different (usually smaller) scale or with structural modifications. A second type of physical models is obtained by turning to a different physical system, e.g., from the original biosystem to a corresponding electrical circuit [407]. Another group represents *verbal models*. They give a linguistic representation of our knowledge about the system, usually formulated as rules, e.g., "IF this or that happens THEN the system reacts by...". They are widely applied in the area of artificial intelligence, namely experts system [408, 409]. In the form of fuzzy-based systems, they gain increasing industrial interest in biotechnological control theory, which is due to their effective treatment of qualitative knowledge of experienced technologists in process control strategies (see Section 8.3.1), which could only hardly realized in terms of mathematical equations [410 – 412]. *Mathematical models* form the third class. They can be classified further depending on the mathematical formalism or the methods for model building. Theoretical models as mechanistic models are based on physical and chemical laws and our knowledge about the inner structure and function of the system. In contrast, experimental or nonmechanistic mathematical models try to give – without

looking into the interior of the system – only a description of the observed reaction of the system in response to a certain forcing signal. Many "mechanistic" models in biotechnology are actually due to their oversimplification quite closer to black-box models than to real mechanistic models, although mostly mechanistic interpretations are given [413 – 415].

White-box model. As described above (Section 8.3.1), the relation can strictly be mechanistic, considering the four differential equations for mass and heat balance and corresponding transformations. In this so-called *white-box modeling* strategy, the model development is mainly driven by the knowledge of the relevant mechanisms, macroscopic balances and predefined parameters. Indeed, if all the biosystem underlying mechanism are known and can be described by means of the above-specified equations and the accompanied parameters are known, the resultant white-box model is generally applicable and show good extrapolation properties. However, it is not an easy task to reveal all the relevant mechanisms and quantify these mechanisms correctly when dealing with biological processes. The *metabolic modeling* approach is one such approach and has been the focus of recent attention [416, 417]. Additionally, several attempts have recently been made in utilizing metabolic information for online identification and control as a consequence of the white-box strategy [418, 419].

Black-box model. The black-box model is, on the other hand, mainly driven by measured data obtained from the process, either online or offline. In terms of mathematical expressions, probability density functions for the important parameters are specified by means of available data. Based upon these distributions, the time-dependent system behavior can be forecasted [420 – 422]. The earliest stochastic biosystem model is perhaps that proposed by Yule, to mimic the evolution of a new species within a genus [423]. However, they are mainly used for systems only, where isolated parameters are treated. It is unrealistic that for a real biological MIMO system (multiple input multiple output), all joint probability densities, which are necessary to describe the key behavior, can be approximated by performed series of experiments. Even for systems without the existence of any driving-force function the expense for their determination is disproportional to the possible result. If inputs exist, which direct the system in a defined direction, reaction patterns must be formulated additionally in terms of probabilistic equations.

Another type of black-box models represents those where a specific functional structure is assumed, which is combined with a subsequent parameter estimation to adapt to the specific underlying problem (e.g., polynomial regression, ANN, chemometric models). However, on applying this, it has to be considered that the simplest and usually fairly accurate method for predicting values of the next data point in a time series from a "well-behaved" biosystem is to assume that it is the same as the present data point, a principle known as the first-order trivial predictor. Similarly, in the second-order trivial predictor the value of data point n+2 is equal to that for point n plus twice the signed difference between the values of point n+1 and n. If any complex nonlinear predictive model like ANN can do no better than the first- and second-order trivial predictors – which are indeed very often concurrently – then their development is a waste of time. Nevertheless, especially ANNs have been the focus of much attention for model development and have already been applied to various biochemical processes (Section 8.3.2). Although the main advantage of the development of black-box models is that a reasonably accurate model can be obtained without detailed mechanistic system knowledge, it should be noted that its accuracy depends only on the quality of the available input and output data. As black-box models are not believed to have any extrapolation properties, one has to obtain a large body of data for process identification by employing the relevant input variables in a wide range of fluctuations [218].

Markov chains. Another very attractive way to use probabilistic approaches are the formulation of the problem by means of so-called Markov chains [424, 425]. A Markov process allows the modeling of uncertainties in real-world systems that evolve dynamically with time without using mechanistic approaches. The basic concepts of a Markov process are those of states of a system and of state transitions. In specific applications, the modeling "art" is to find

an adequate state description such that the associated stochastic process has the Markovian property that the knowledge of the present state $X(t)$ is sufficient to predict the future stochastic behavior of the system $X(t+1)$. The moving of $i=t$ to $j=t+1$ is defined by means of the transition probability P_{ij} [426]. For bioprocess engineering, controlled Markov chains or Markov decision processes (MDP) possess a high potential, for simple modeling as well as for process optimization [427, 428]. Applied in bioprocess engineering, they involve the selection of an action U_t from a set of containing a finite number of A actions when observing the current state of the system. The problem is to define the probability that the system goes to a state j from a state i under the action of a:

$$P\{X_{n+1}=j|X_n=i,U_t=a\}=P_{ij}(a) \tag{19}$$

The controlled Markov chain is completely defined by the optimality criterion for calculation of the transition probability matrix, the state vector X, the action set A, and the decision epoch. For bioprocess modeling, concentration values grouped in clusters are often used as state variables; considering more than one state variable for each one a separate model is constructed. One great disadvantage of this approach represents the huge effort to determine the transition probability matrix P_{ij}(a) for each control action, especially if more than one manipulated variable should be considered [428].

Grey-box model. A grey-box model may be defined as a suitable combination of a black-box principle and a white-box model. The expectation is to obtain good interpolation and extrapolation properties. Especially, hybrid approaches, where portions from each principle are pieced together based upon the amount and the structure of available knowledge, gain increasing importance. From different points of view, such hybrid systems can be build up, i.e., analog or discrete consideration, stochastic or deterministic combinations [429 – 431]. Only some important concepts for bioprocess engineering should be presented here. In some cases, statistical methods are included into a mathematical discrete formulation, this concerns mainly *Kalman filtering*. They exploit statistical information about the error distribution of the state and a measurement values, and their propagation with time to predict online a future state based upon new measurements and already existing quantities. Their potential in bioprocess modeling and control is obvious [432 – 434].

From the structural point of view, hybrids are described in parallel and serial configurations. In the former case, the black box is placed in parallel with a white-box model and its role is to describe and to weight the difference between a white-box model and the real process. This model has been applied to several processes, but its performance might be limited to some extent to the viewpoint of extrapolation properties [435]. In the serial structure, the black box is placed in series with a white-box model. Different applications are described. Combined with a fuzzy expert system, the hybrid was applied to model a real-time fed-batch culture for baker's yeast production, a production scale beer-brewery fermentation, and mammalian cell cultures [431]. To show the better extrapolation properties of grey-box-model exemplarily, the performance of a serial-type grey-box model containing a neural network and a more knowledge-driven white-box model were compared with that of a more data-driven black-box model in the enzymatic hydrolysis of penicillin G to 6-amino-penicillanic acid and phenyl acetic acid by using the enzyme penicillin acylase. The grey-box model was shown to have significantly more reliable extrapolation properties than the black-box model [436].

Also linguistic models such as fuzzy models can be seen as a special type of grey-box models. Although the intrinsic behavior cannot be formulated by means of mathematical equations, a priori knowledge is included into the model by the linkage of various "IF. . .THEN . . . " conclusions, which is built up by the knowledge of highly specialized staff. Their fine-tuning is often accomplished by using data from experiments [437].

Being aware that different approaches exist how biological systems can be modeled and treated computationally, an important aspect for a successful application is the proper choice which principle fits best to the specific problem and its boundary conditions. In most cases, more than one specific approach can be applied in principal. The most important aspect for choos-

Table 16. Different types of models based upon the system knowledge

High	System knowledge				Low
Model	deterministic	stochastic, statistical	expert systems	approximation	classification
Examples	unstructured, structured, CFD[a]	Markov chains, maximum likelihood, Kalman,	fuzzy models, set theory	neural networks, PLS[b], PCR[c]	pattern recognition

[a] CFD, computional fluid dynamics.
[b] PLS, partial least square.
[c] PCR, principal component regression.

ing the right model should be the system knowledge about the underlying problem (Table 16).

Not only the amount of system knowledge is decisive, but also its structure, the quality and quantity of accompanied data, and the purpose for which the model should be used is of special importance. As a basic principle for building up a model, it could be postulated "use as much a priori information as possible". In mechanical engineering and fluid dynamics, strictly deterministic approaches are typical, where the underlying differential equations are "exactly" known. Thus, there exists no reason to deal with uncertainties and the problem is forwarded. However, this situation generally does not exist in bioprocess engineering. A biological system consists of a very complex, strongly regulated reaction network, where only some simple mechanisms can be formulated in terms of mathematical discrete forwarded formulations. Thus, one has to deal in a very strong degree with uncertainties. If one is able to formulate a set of differential equations, which represents not an exact image of the underlying mechanism but is descriptive enough for the existing problem and for the modeling purpose, one should formulate such a model and append a subsequent parameter estimation step where statistical properties or available data are exploited to consider unknown or not structural included information. In the case where a formal-kinetic approach cannot be formed but qualitative knowledge is available or can be extracted from available data, expert systems should be preferred. Especially fuzzy systems as a special representation of an expert system show advantages in modeling approaches because of their smoothness concerning the system output. In the case where a priori knowledge of the system is not available but pure data from a well-defined experimental design do exist, approximation or classification approach like ANN or chemometric models should be used. In those cases, they are the only alternative to realize appropriate prediction ability. They assume a system structure, which possesses no causal relation with the underlying real mechanism, but is able to incorporate and describe the system dynamics. They possess normally good approximation abilities, but their extrapolation property reveals a low reliability especially if outputs should be forecasted where the corresponding inputs are outside of the trained data space.

9. Special Applications in Biotechnology

The following chapters highlight some special aspects in biotechnology. However, there exist even more interesting applications in biotechnology. The reader should regard the areas chosen by the authors as examples for the wide distribution of biotechnology in the daily living.

9.1. Mammalian Cell Culture Technology

9.1.1. Introduction

Mammalian cell culture technology has become a major field in modern biotechnology, especially for the area of human health, and fascinating developments achieved in the last decades are an impressive example for an interdisciplinary interplay between medicine, biology, and engineering [438, 439]. Among the classical products from cells, we find viral vaccines, monoclonal antibodies, interferon, as well as recombinant therapeutic proteins. Tissue engineering or gene therapy open new, challenging areas [440].

Under "mammalian cell culture" or "animal cell culture" is to be understood the cells of a mammalian, isolated from specific tissues (i.e., skin, liver, glands, etc.) and further cultivated and reproduced in an artificial medium (Fig. 31) [441, 442]. During cultivation of mammalian cells in vitro, outside of a living organism, some distinct difficulties arise from the extraction of the cells from a "safe" tissue. Slow growth rates with doubling times between 18 and 28 hours, low productivity, a high sensitivity against shear stress due to the lack of a cell wall [443] and high demands in respect to the growth medium challenge the techniques required for mammalian cells. Furthermore, many cell lines grow adherent, and a suitable surface for attachment must be provided for these cells to proliferate. As of the origin from multicellular organisms, mammalian cells still hold the genetic program of inducing their own cell death, a process called "apoptosis" or "programmed cell death" [444 – 446]. This can limit culture productivity in biotechnological processes. Another major problem is the finite lifespan of primary cells, which die after several doublings in vitro. This problem was solved by transforming primary cells into immortal "established" or "continuous" cell lines. The engineering targets related to mammalian cell culture technology can be identified as:

– Production of a valuable product (viral vaccine, protein) from mammalian cells, development of processes for the efficient production of the desired product from a laboratory to a industrial scale under the restrictions given by the cell properties (*products from cells*).
– Development of processes for the cultivation of organic tissues, which can be used as substitute to original tissues (tissue engineering, gene therapy, *cells as products*).

Much effort has been put into the development of mammalian cell culture technology, and great progress was achieved in the last decades [447, 448]. Mammalian cells may now be cultured to very large volumes (up to 20 000 L) to provide the necessary quantities of a desired protein. Media that used to contain up to 10 % serum were continuously improved, and the cultivation in defined serum-free and even chemically defined, protein-free media is now common for most relevant industrial cell lines. Bioreactors were developed that provide the required low-shear-stress environment by, e.g., introducing gentle agitation and aeration with slow moving stirrers in stirred tanks, designing special aerators for air-lift reactors, or by separating the cells from the stressful conditions such as hollow-fiber, fluidized-bed, and fixed-bed reactors. In industrial scale, adherent cell lines can be cultivated on microcarriers (e.g., for vaccine production) or are adapted to grow in suspension, e.g., cell lines derived from baby hamster kidney cells (BHK) or chinese hamster ovary cells (CHO).

Figure 31. Morphology of (a) suspendable and (b) adherent mammalian cells (bar approx. 30 µm)

Genetic engineering contributes a great deal to recent progress [449 – 451]. With this technology, functional proteins can be produced by introducing recombinant DNA into cell lines, e.g., chimeric (humanized) antibodies are produced for in vivo applications in transfectoma or recombinant CHO cells. New promoters have been developed to enhance productivity, and product titers over one gram per liter have been reported for some industrial cell lines. Further, novel cell lines can now be constructed from

primary cells without loosing functionality by genetically induced proliferation [452, 453].

The following will provide a basic understanding of the specific requirements of mammalian cells, will describe state of the art process technology for cultivation of these cells and will give an outlook to future prospective. A comprehensive overview on cell culture technology is given by OZTURK and HU [454].

9.1.2. Products from Mammalian Cells

A detailed overview on products from mammalian cells is given in [454, 455]. Within "products from cells", viral vaccines [456] against polio, hepatitis B, measles, or mumps for human use, rubella, rabies, or food-and-mouth disease (FMD) for veterinary use play an important role. Viral vaccines are produced very efficiently by means of a cell-based vaccine technology. For this, mainly primary cells, diploid cells, or permanent cell lines (e.g., VERO) are applied, recently even recombinant cell lines. A breakthrough for the large-scale production of viral vaccines with anchorage dependent cells was the development of microcarriers in the late 1960s, allowing cultivation in stirred tanks in thousand-liter scale. New targets for cell-based vaccines are human immunodeficiency virus (HIV), herpes simplex virus, or influenza. Furthermore, new developments include genetically engineered or DNA vaccines (→ Immunotherapy and Vaccines).

Monoclonal antibodies [457] have become a valuable tool for diagnostic purposes as well as in therapy. Antibodies synthesized by B-lymphocytes play an important role in the immunosystem of mammalians. Traditionally, polyclonal antibodies were isolated from blood samples. In the 1970s MILSTEIN and KÖHLER developed a technology to generate hybridoma cells producing monoclonal antibodies [458]. As of the specific binding, monoclonal antibodies are widely used for diagnostics, where tens of thousands different monoclonal antibodies are available. The importance of monoclonal antibodies as therapeutic agents has evolved only recently, as immunogenic mouse antibodies were replaced by chimeric, humanized, or human antibodies. Fields of application are organ transplantation (OKT3), cancer diagnostic and treatment, rheumatoid arthritis, leukaemia, asthma, or multiple sclerosis. Nowadays several antibodies are produced in kilogram quantities [440]. Modern recombinant techniques focus on new antibody formats such as fragmented antibodies (FAbs) or bivalent antibodies with a broad spectrum of applications.

Glycoproteins are a further important group of products produced by mammalian cells. Starting with the production of α-interferon as an anti-infectious drug by (nonrecombinant) Namalwa cells in the late 1970s, nowadays a growing number of glycoproteins for treatment of a wide variety of diseases are produced by means of mostly recombinant mammalian cells. Prominent examples are cytokines (e.g., interferons and interleukins), hematopoetic growth factors (e.g., erythropoeitin for treatment of anemia), growth hormones, thrombolytic agents (e.g., tissue plasminogen activator [tPA]), coagulation factors (factor VII, factor VIII, factor IX etc.), and recombinant enzymes (DNAse) [440].

Recombinant proteins may be produced by either bacterial, yeast, or mammalian cells. From a technological point of view, hosts such as bacteria or yeast have an advantage with respect to growth rate, final cell density, and product concentration. Nevertheless, mammalian cells are preferred for those proteins requiring a specific, humanlike glycosylation pattern [459, 460], which is difficult to obtain in other host systems. Another problem for microorganisms is the maximal size of the produced protein which must be below a molecular mass of approx. 30.0 kDa. Further, in contrast to extracellular release of most proteins produced in mammalian cells, products from microorganisms are often accumulated intracellularly in "inclusion bodies". This demands a more complex downstreaming. Besides this, for mammalian cells important parameters such as product yield, medium requirements, and growth characteristics (suspendable, shear resistant) have been significantly improved.

Proteins produced in the milk of transgenic animals have started to compete against "classical" mammalian cell culture [461 – 464]. The proteins are usually expressed in enormous titers, over one order of magnitude higher than that obtained from cell cultures. The price for the production in transgenic animals will probably continue to decrease significantly due to

the development of more efficient reproduction technologies. These new approaches will significantly decrease the time for the development of a product. Among the disadvantages of transgenic animals, we find a more sophisticated downstreaming (high protein loads), the long development time, the inability to produce proteins that might impair the health of the animal (e.g., insulin), higher risk of viral contamination and the possibility of prion contamination (scrapie, BSE).

The novel field *cells as products* includes the development of artificial organs (tissue engineering of liver, kidney) and tissues (skin, cartilage, bone), or the expansion of hematopoietic cells for bone marrow transplantation or gene therapy. The exciting prospects of *tissue engineering* [465 – 467] are outlined in Section 9.2. *Somatic gene therapy* implies transfection of a specific gene to cells isolated previously from a patient suffering from a genetic disease [468 – 470]. The transfected cells are then reintroduced into the patient. Gene therapy involves transfer of genetic material, encoding therapeutic genes and the sequence necessary for expression to target cells to alter their genetic code for a desired therapeutic effect. Many diseases are originated by gene defects. Expression of the transferred genes can result in the synthesis of therapeutic proteins or correction of a gene defect. Gene transfer could also lead to desired apoptosis or inhibition of cell proliferation. Theoretically, gene therapy can be applied for repairing single entailed gene defects, acquired gene defects such as chronic infectious diseases, multifactor genetic diseases such as cardiovascular disease, and finally cancer. Since gene therapy was applied the first time in 1990, the number of clinical trials increased. Today gene therapy is widely used in ongoing clinical trials for the treatment of cancer and infectious diseases such as human immunodeficiency virus (HIV) infection.

Cell culture products are currently used mainly as medicines or in diagnostics. For medicines, some products have a demand of 500 kg/a and generate $ 1–2 billion dollars in revenue. Among these are tissue plasminogen activator (tPA), erythropeithin (EPO) products, Remicade® (Centocor) or MAbThera® [440]. The pipeline for new biopharmaceutical therapeutics targets a huge number of diseases (e.g., 425 for U.S.A in 2002 [471]), most of them for cancer therapy, infectious diseases, autoimmune diseases, or AIDS/HIV. It can be expected that at least some of these will find their way to the market. Furthermore, new products or medical protocols can be expected for tissue engineering and cell therapy. As for some compounds patents are already expired or will expire in the near future, there will be a market chance for biosimilar or generic products. On the other hand, the costs for target identification, clinical trials, and process development will increase (to date approx. $ 0.5–1 billion) and only block busters will make it finally to the market.

9.1.3. Cell Types

In general, mammalian cells relevant for industrial processes can be divided into the following groups [441, 472]:

- *Primary cells* have been isolated from a tissue and than taken into culture (primary culture).
- *Permanent or established cell lines* originate from a primary culture, but because of some transformation became able (at least theoretically speaking) to divide and proliferate indefinitely. Those cell lines are kept in a cell bank and are very often used as host cells for the expression of recombinant proteins.
- *Hybridoma cells* are cells which are obtained through the fusion of lymphocytes and tumor cells and which are able to express monoclonal antibodies.

The common procedure for the isolation of a mammalian cell from a tissue involves the following steps: first, a small piece of tissue is decomposed into single cells or cell clots mechanically, enzymatically (e.g., typsin [473], collagenase), or through a combined procedure. The cells are separated from the enzymes by centrifugation and resuspended in culture medium. After that, the cells are inoculated into a special glass or plastic vessel with flat bottom. The anchorage-dependent cells start to adhere to the bottom surface and, after a lag phase, start to divide by mitosis. Such a cell culture, in which the cells come from a differentiated tissue, is called a primary cell culture. The most critical point in the isolation of primary cells is to avoid external contamination by practicing aseptic techniques.

When the primary cells have covered the bottom of the culture vessel almost completely, they are enzymatically cleaved (i.e., trypsin) from their support and used to inoculate new cultures. This subculture gives origin to the so-called secondary cultures. Part of the cells is stored deeply frozen in liquid nitrogen, to remain as a safety stock, from which it is possible, at any time it might be necessary, to get enough "fresh" cells to start a new series of subcultures for mass production. With the primary cells, it is possible to repeat subcultures several times. However, the primary cultures have a finite lifespan and therefore, after a certain number of doublings (from 50 to 100 times), the cells cease to grow and die [441].

A finite growth capacity is a characteristic of all cells derived from normal mammalian tissue. A cell can be considered as normal when it shows a certain set of characteristics [474]:

- *A diploid number of chromosomes* (i.e., 46 chromosomes for human cells) with which it is shown that no gross chromosome damage has occurred.
- *Adherence*: the cells require a surface to grow attached to (anchorage dependent). The growth phase extends until the cells reach a stage of confluence (contact inhibition).
- *A finite life span* in culture.
- *Non malignant*: the cells are not cancerous, i.e., they do not cause tumor in mice.

In the 1960s, normal cells were required for the production of human vaccines in order to ensure the safety of these products [441].

Not all cell types produce exclusively primary cell cultures, which after a limited number of "passages" die. Some cells acquire an infinite lifespan and such a population is usually called a "permanent" or "established cell line" (Table 17). These cells have undergone a "transformation", i.e., they have lost their sensitivity to the growth control mechanisms. Transformed cells can also lose the characteristic to grow adhered to a surface and thus become able to grow in suspension. These transformations are also sometimes reflected in the chromosomes, changing the genotype of the cells. Transformed cells can be easily grown in relatively simple media without addition of expensive growth factors. At first, transformed cells were identified just by chance, but nowadays there are techniques to cause cell transformation and "immortalisation", as for example the treatment with mutagenic substances, with virus or with oncogenic substances [441]. Transformation of cells in vitro shows some similarities with carcinogenese in vivo, but is not identical to it; for instance, not all the transformed cells are malignant. On the other hand, all cells that are isolated from tumors (i.e, HeLa or Namalwa Cells) can be kept in a permanent culture.

Table 17. Examples of permanent cell lines important for research and production (data from [441], modified)

Cell Line	Origin	Application
Baby hamster kidney BKH-21	syrian hamster, 1963	adherent cells, but can be adapted to suspension, FMD vaccine, rabies vaccine, recombinant proteins (Factor VIII)
Chinese hamster ovary, CHO-K1	ovary of chinese hamster, 1957	adherent cells, but can be adapted to suspension, recombinant proteins (HBstg, tPA, Factor VIII)
COS	monkey kidney	transient protein expression [475]
NAMALWA	human lymphatic tissue	alpha-interferon
HeLa	tumor in a cervical vertebra	Fast-growing tumor cell line that was isolated in the beginning of the 1950s.
HEK-293	human embryonic kidney, 1977	transient protein expression
MDCK	rabbit kidney	adherent cell line with good growth characteristics, animal vaccines
MRC-5	human embryonic lung cells	"normal" cells with a finite life span, vaccine production
NS0 and SP2/0	mouse myeloma from B-lymphocytes	antibody production
3T3	mouse connective tissue	suspensible, used in the development of the cell culture technology
WI-38	human embryonic lung cells	"normal" cells with a finite life span vaccine production
Vero	long-tailed monkey kidney, 1962	established cell line, but with some characteristics of the normal diploid cells.

Hybridoma cells are "artificial" cells produced by the fusion of human or mammalian lymphocytes, which can secret specific antibodies, with a myeloma cell. Usually, lymphocytes do not survive outside the original organism, i.e.,

cannot be kept alive in an artificial medium. MILSTEIN and KÖHLER [458] were able to overcome this problem by fusing a mouse myelom cell similar to a tumor cell with a lymphocyte from a mouse spleen, which was able to produce antibodies. The cells generated in this way are hybrid cells (also called "hybridoma cells") and have the lymphocyte characteristic to produce antibodies against a certain antigen, as well as the ability from the myelom cells to survive in culture.

An alternative expression system for recombinant proteins offer insect cells, especially the insect-cell baculovirus expression system (ICBEVS) [476]. Mostly applied are Sf9- or Sf21-cells isolated from *Spodoptera frugiperda*. Production of heterologous proteins by the ICBEVS consists of two stages. Insect cells are first grown to a desired concentration and then infected with a recombinant baculovirus containing gene coding for the desired protein. Meanwhile, several recombinant proteins produced by this technique have reached the market.

The largest and most well known international animal cell culture collections are the American type culture collection (ATCC) [477], the European collection of animal cell culture (ECACC) [478] as well as the German resource centre for biological material (DSMZ) [479].

The application of permanent cell lines for the production of vaccines faced strong opposition, mainly in the 1960s, because there was the suspect that these cell lines, which behave similarly to tumor cells, could infect patients with unknown cancerous substances. Fortunately, no observation of this kind has been done until today. In the meanwhile, more and more permanent cell lines have been applied for the production of therapeutic and diagnosis substances. However, the application of permanent cell lines, and above all, of recombinant cell lines, is strictly controlled by supervisory boards (as the FDA [480] in the USA, and the EMEA [481] within the EU). During the whole production cycle of a pharmaceutics, not only the product has to be identical from charge to charge, but also the phenotypical characteristics of the cell line has to be maintained. To assure that, before the beginning of the production, a "master cell bank" has to be created, from which a "master working cell bank" is derived, providing the inoculation material for the production cultures.

9.1.4. Growth Medium for Cell Culture

Basically, a growth medium for mammalian cells have to supply all the necessary nutrients required for growth and product formation [482, 483]. Furthermore, it should have a certain buffer capacity to stabilize the pH (pH optimum 7.0–7.3) and should provide an appropriate osmolality in order to avoid damaging of the sensitive cell membrane [484 – 488]. A fundamental component of all media is a salt solution, which provides the ions necessary for life, keeps the osmotic pressure within the desired range, contains one or more buffer systems (sodium phosphate buffer, HEPES, and/or carbon dioxide–carbonic acid buffer) for pH regulation, and contains, in some cases, a pH indicator (phenol red). Furthermore the media contain glucose and glutamine as a source of carbon and nitrogen, other amino acids, vitamins, mineral salts, and trace elements.

A number of medium formulations have been developed, e.g., Eagle's minimal essential medium (MEM), Dulbecco's enriched (modified) Eagle's medium (DMEM), Ham's F12, and RPMI 1640, among others. Examples of medium compositions can be found in the literature [442, 454, 489]. Traditionally these basic media were supplied with approx. 5-10 % serum (e.g., foetal calf serum [FCS] or horse serum [HS]) in order to supply specific growth factors and to protect the cells against shear stress. The disadvantage of media containing serum are the indefinite composition of such media, the high serum costs, the difficulty of product purification, variations between the charges and the risk of virus contamination [490].

Serum can be partially substituted by the addition of transferin, insulin, ethanol amine, albumin, or eventually fibronectin as adherence factor in a serum-free but still protein-containing medium [491 – 493]. A further step to chemically defined, protein-free media became possible by replacing these animal-derived proteins by iron salts or iron complexes, IGF-1, chemically defined lipid concentrates, precursors or other stimulating agents such as fatty acids, biotin, cholin, glycerin, ethanolamin, thiole, hor-

mones, and vitamins [494 – 496]. Furthermore, addition of peptone or yeast extract can be helpful [497, 498]. However, the growth rate and productivity in a serum-free medium can decrease [499]. In addition, the sensitivity to shear stress increases, requiring additives with protecting characteristics, such as Pluronic F68 [500, 501]. Immobilization can improve the culture stability of nonanchorage-dependent animal cells grown in serum-free media [502, 503]

Different cell lines require different compositions. Adaptation of a cell line to grow without serum is quite time-consuming and not all cell lines have been adapted to serum-free or protein-free media [504, 505]. For cultivation of primary cells, for basic cell-culture research or for vaccine production still mostly complex, serum-containing media are common. In industrial production with established, optimized cell lines, serum-free, bovine-serum and protein-free as well as chemically defined media are state of the art [439].

9.1.5. Small-Scale Culture Systems for Routine Use

Techniques and culture systems for cultivation of mammalian cells differ significantly from those used for microbes. For basic research, a large number of culture systems have been developed (Fig. 32), mostly designed for use in an incubator aerated with 5 % CO_2 to maintain the pH within the desired range. Multiwell plates (6–96 wells), T-flasks (25–100 mL), Petri dishes or roller bottles (50 mL to 5 L) are usually used for cell maintenance and proliferation, especially for adherent cells [441, 506 – 509]. These systems allow for sterile handling procedures and are easy to use, disposable, and low-cost. On the other hand, they require individual handling, for example in medium exchange and cell seeding; their usefulness is limited when large quantities of cells or products are required. This can be overcome to some extent by using sophisticated robotics [510]. Furthermore, environmental parameters including pH, dissolved oxygen, and temperature can hardly be controlled within the medium. A further drawback

Figure 32. Routine cultivation systems for use in incubators

is the limited increase in cell number (approximately 10-20 times during cultivation). Alternatively, small well mixed bioreactors (for example, shake flasks, stirred vessels, and "super spinner" [511]) can be used, where adherent cells are grown on microcarriers.

Microcarriers are small beads, either solid or macroporous, having a diameter of approx. 100-300 μm and a density slightly higher than the growth medium. When first developed in the late 1960s [512 – 515], microcarrier culture introduced new possibilities and suspension culture of anchorage-dependent cells in high density. Nowadays, beads made of DEAE-Sephadex, DEAE-polyacrylamide, polyacrylamide, polystyrene, cellulose fibers, hollow glass, gelatin, or gelatin-coated dextran beads are in use [442]. In microcarrier culture, cells grow as monolayers on the surface of small spheres (Fig. 33) or as multilayers in the pores of macroporous structures that are usually suspended in culture medium by gentle stirring. By using microcarriers in simple suspension culture, fluidized or packed-bed systems, yields of up to 200×10^6 cells per milliliter are possible [516]. Microcarriers are extensively used for vaccine production on a larger scale (see below) [517 – 521].

Figure 33. Porcine chondrocytes grown on microcarriers (Cytodex 3, GE Healthcare)

Microencapsulation is another method for the immobilization of mammalian cells [441]. Basically, it can be used to protect cells against hazardous environmental conditions. The three basic encapsulation systems existing are the bead, the coated bead, and the membrane-coated hollow sphere [522 – 524]. Typical size for beads made of polysine alginate is 300 to 500 μm, and the molecular-mass cutoff of these capsule membranes is 60 to 70 kDa [442]. The capsules can be cultivated in suspension reactors similar to microcarriers. Detrimental with respect to scale-up is the fragile nature of the microcapsule.

In membrane bioreactors, including small hollow-fiber reactors [525], the miniPerm system [526] or the tecnomouse [527], cells are cultivated at tissuelike densities in a compartment which contains one or several types of membrane for nutrient and oxygen supply and removal of toxic metabolites. Hollow-fiber systems (compare Section 9.1.6) are widely used in the production of biopharmaceuticals including monoclonal antibodies. Several examples of modified membrane bioreactors exist for the three-dimensional culture of tissue cells [528 – 530] including hepatocytes [531 – 533], skin cells [534], or other human cells [535]. The specific characteristics of hollow-fiber reactors are discussed below.

9.1.6. Types of Bioreactors

Design and selection of cell culture bioreactors for larger scales have to meet special demands such as gentle agitation and aeration without cell damage, a well controlled environment with respect to pH, temp, dissolved oxygen, dissolved CO_2 concentration etc., low levels of toxic metabolites (ammonia, lactate), high cell and product concentrations, optimized medium utilization, surface for adherent cells, and scalability [536 – 545]. Bioreactors for mammalian cell culture can be divided into two categories (Fig. 34): *Low-density* or homogeneous systems (stirred-tank, bubble-column, air-lift reactor), where cells are cultivated either in suspension or, if required, on microcarriers; and *high-density* or heterogeneous systems (fixed-bed, fluidized-bed, hollow-fibre reactor), where cells are immobilized either in macroporous sup-

Figure 34. Bioreactor systems for cultivation of mammalian cells

port materials or within a compartment created by membranes. Selection of a reactor systems depends to a large extent on the specific purpose such as production of a certain amount of protein (small amounts for basic scientific studies up to kilogram quantities for medical application), three-dimensional tissue cultivation, or single-purpose or multipurpose facility.

Design of suspension reactors has to deal mainly with cell damage due to shear stress caused by agitation and/or aeration [546 – 548]. Stirred-tank reactors (Fig. 35), which are the most common type of reactor and are nowadays build up to 20 000 L scale, are especially suited for suspendable cells [549]. Adherent cells can be grown on microcarriers and by this handled similar to a suspension culture (see Section 9.1.5). For mixing, standard impellers (e.g., rushton turbine, pitched or marine impeller) as well as large paddle impellers are used depending on the shear sensitivity of the cells, sometimes combined to achieve a homogenous mixing throughout the bioreactor at lowest possible stirrer speed [441, 549]. For aeration, different methods are shown in Figure 36 [550 – 552]. Surface aeration can be applied only for low cell densities and volumes (below 1 L). Bubble aeration may cause cell damage mainly due to foam formation, especially in case of serum-containing medium. By applying special aerators (ring sparger, microsparger) in combination with serum- or protein-free medium,

the detrimental effects of bubble aeration can be overcome [553 – 556]. Alternatively, bubble-free membrane aeration systems were developed [557 – 560]. They are characterized by low shear rates, but require large membrane areas. On laboratory scale, a tumbling membrane basket can be used for mixing [511]. Rotating/vibrating sieves provide a gentle aeration, but are suitable mostly for laboratory scale [561]. *Bubble-columns* and *air-lift reactors* were build up to thousand liter scale, are easy to handle, but require serum-free media to prevent cell damage through bubbles and foam [549, 562]. For continuous operation of stirred tank reactors in perfusion mode (see Section 9.1.7), several techniques for cell and/or product retention are in use as shown in Figure 37 (e.g., microfiltration and ultrafiltration, sedimentation, centrifugation, spin filters, acoustic filter, dialysis for cell, and product enrichment [563 – 577]). *Suspension reactors* are characterized by advantages such as: conventional reactor systems, know-how on design and sterile operation, good mass transfer, homogeneous mixing, possibility of sampling and determination of the concentration of the cell, and high scale-up potential. Disadvantages are: difficult oxygen supply at high cell densities, cell damage by shear and/or foam (bubble aeration), relatively high demand for control (temperatur, oxygen, pH, flow rates), cell retention required for h igh cell densities.

Among high-density systems, we find *fixed-bed* and *fluidized-bed reactors* as well as *hollow-fiber reactors*. In fixed-bed and fluidized-bed bioreactors, cells are immobilized within macroporous carriers. The carriers are arranged in a column either packed (fixed-bed reactor [578 – 584]) or floating (fluidized-bed reactor [585 – 587]). The column is permanently perfused with a conditioned medium from a medium reservoir, mostly in a circulation loop. These types of reactor are very efficient for the long-term perfusion culture of mammalian cells for the production of biopharmaceuticals (e.g., monoclonal antibodies, recombinant drugs including tPA and EPO). With respect to tissue engineering, they have been investigated for several applications including the cultivation of "liver" cells as an extracorporal liver device [588 – 590] or proliferation of stem cells [591 – 593]. Furthermore they were successfully used for cultivation of cells producing viruslike particles for gene therapy [594 – 597]. Again, scale-up is critical for both fixed-bed and fluidized-bed reactors. For fixed-bed reactors, a radial-flow fixed-bed geometry was suggested [598 – 600] and successfully applied up to approximately 25 L fixed-bed volume. At perfusion rates of 10-20 L L_{FB}^{-1} d^{-1}, this would correspond to suspension reactors in the thousand liter scale. Alternatively, rotating-bed bioreactors are in use [601]. For fluidized-bed bioreactors, several concepts for scale-up have been suggested as well [514, 585 – 587, 602]. Compared to suspension reactors, fixed-bed and fluidized-bed reactors have the following advantages: high volume-specific cell density (approx. 5×10^7 cells/mL reactor) and productivity, low shear rates, simple medium exchange and cell/product separation, productivity on a high level during long-term cultures. Disadvantages are: nonhomogeneous cell distribution, difficult determination of cells and cell harvest.

Figure 35. Multipurpose bioreactor for continuous perfusion culture of mammalian cells (Bioengineering AG, CH-Wald, with permission)

Within *hollow-fiber reactors* (compare Section 9.1.5), cells are immobilized in the extracapillar space of a hollow-fi4ber bundle. Nutrients as well as oxygen pass through the fibers, metabolites leave the culture chamber by this way. Cell concentrations comparable to those found in tissues are possible. The use of hollow-

fiber culture is a convenient method for making moderately large quantities of high-molecular-weight products secreted by human and animal cells, at high concentrations and with a higher ratio of product-to-medium-derived impurities than is generally achieved using homogeneous (e.g, stirred-tank) culture [603 – 605]. Advantages are: very high cell densities, concentrated product, lower serum demands (if required), long-term stability, easy handling, and low cost. Disadvantages are: limited scale-up, mass-transfer problems/concentration gradients, difficult determination of the cell number, proteolytic activity on the product.

During the last years, a growing number of disposable or single-use bioreactor systems appeared on the market besides hollow-fiber reactors, addressing especially problems related to early process development such as flexibility, cost effectiveness, time-to-market as well as quality and regulatory issues [606 – 608]. These systems are mostly based on a bag technology [609, 610]. The bags with volumes up to 250 L are placed on tilting or rocking devices for mixing and oxygen supply. Advantages of single-use bioreactors are reduced cleaning procedures, lack of validation issues (cleaning, sterilization, etc.), lower investment costs, easier adaptation to changing process demands, less contamination risk [611 – 613].

The main characteristics of the culture systems discussed above are summarized in Table

18. All these systems support growth of mammalian cells in one or the other way. On laboratory scale, mostly disposable flask, membrane, or bag systems are the method of choice. Small suspension reactors as well as fixed bed and fluidized bed reactors are mostly used for research or process development. For larger amounts of products, only suspension reactors or, up to a certain scale, fixed-bed or fluidized-bed reactors have the required scalability. For a detailed discussion, compare [440, 555, 614 – 618]. Bioreactor design, in particular, is addressed in [619].

9.1.7. Process Strategies

As for all biotechnological processes, process strategies for operation of bioreactors can be classified in discontinuous (batch, repeated-batch or fed-batch) and continuous modes (chemostat, perfusion). Batch and fed-batch processes are mostly performed in small-scale culture systems (e.g., flasks, bags) or on larger scale in suspension reactors. Batch processes are usually starting with an initial cell density of approximately 1–2 10^5 cells mL^{-1} and last 1–2 weeks. After harvest, the bioreactor has to be cleaned and refurbished before the cycle is repeated [438, 440, 441]. Cell and product yield can be significantly improved by applying a fed-batch strategy, were nutrients are added after depletion according to an appropriate feeding strategy [[621 – 634]. Batch and fed-batch strategies are applied quite frequently on industrial scale [438, 440, 536].

The drawbacks of discontinuous modes such as large reactor volumes, high maintenance (cleaning, sterilization, etc.) can be overcome to some extend by using continuous mode, especially perfusion with cell and/or product retention [438, 563]. Chemostat cultures without cell retention are a valuable tool for research (e.g., kinetic studies) [635 – 639] but not for production scale because of low cell and product concentration. Continuous perfusion present several advantages over batch systems [563, 640 – 643]. The advantages include the ability to grow cells to a very high density, the ease of handling media exchanges for the purpose of fresh feed and product harvest, the easy removal of metabolites and other inhibitors, and the prospect of easy scale-up. When dealing with adherent cells, perfusion reactor design becomes slightly simpler (e.g., fixed-bed and fluidized-bed) because of the immobilization of cells within macroporous carriers (compare Section 9.1.6). There is a growing number of reports on stable perfusion cultures even on an industrial scale over periods of several months [563, 644 – 646]. The main advantage of perfusion cultures can be seen in the reduced bioreactor size (approx. 1/10 of a suspension reactor without cell retention). Nevertheless, there are some difficulties in the perfusion concept [438, 563]. Further equipment such as the retention device itself, pumps for feeding, harvest, and medium circulation, storage tanks for feed and harvest are required. The amount of media needed to complete a moderate to long-term run can be excessively large. A further possible drawback of continuous cultivation is the possibility for variability over the time of the run. Batch or fed-batch cultivations are much shorter in duration and have fewer chances for random occurrences to happen. This is important in dealing with current manufacturing practice (cGMP, see below) conditions that dictate precise reproducibility or at a minimum the evidence of non-effects of minor deviations. In the meantime, there is a growing number of pharmaceutical products in the market, produced successfully from perfusion systems. Among these are block busters such as Kogenate-FS® (Bayer Health Care) or Remicade® (Centocor) [563]. Previous concerns about getting such processes approved are not longer an issue and it can be expected that because of an increasing pressure on production costs more perfusion processes will be installed in the future.

A process that becomes more and more important for production of small quantities of recombinant proteins is *transient transfection* [647 – 649]. Usually, nontransfected cells (most commonly HEK-293, COS, and BHK cells, compare Section 9.1.2) are first cultivated in batch mode to a certain cell density and then transfected with DNA encoding for a certain protein [441]. Usually, the cells are genetically not stable and soon lose their expression ability but can produce a certain amount of protein within one batch. Originally, it was used just as a preliminary test of gene expression. New developments show that large scale production up to 100 L is possible [650, 651].

Table 18. Main characteristics of cell culture systems and bioreactors ([620], modified)[a]

	T-flask/roller bottles/disposable bags	Membrane reactors (hollow-fibre, miniPerm, etc.)	Suspension (stirred-tank, air-lift reactors)	Fixed-bed/fluidized-bed reactors
Cell density	1	3	2	2–3
Homogeneity	1	1	3	2

Steam sterilizable	N	N	Y	Y
Reusable	N	N	Y	Y

[a] 0, not possible; 1-3, increasing efficiency; Y, yes; N: no.
[b] Additional equipment for cell retention required.

9.1.8. Downstream Processes

The desired protein product, mostly extracellular, has to be purified after cell cultivation by a combination of unit processes. From an engineering point of view, the challenges are 1) low product concentrations in the cell-free supernatant, 2) the complex structures of the proteins, especially the recombinant, glycosylated proteins, resulting in a high sensitivity against temperature, shear forces, extreme pH, or proteolytic activity, 3) contamination by nucleic acid (DNA fragments from dead cells), 4) contamination by other proteins (e.g., from serum), 5) potential contamination by viruses or virus particles [652, 653]. The main process steps involved are [654]: concentration of supernatant (e.g., precipitation, centrifugation filtration, or aqueous two-phase partition), primary purification/capture (e.g., chromatographic techniques such as ion-exchange, gel, or immunoaffinity chromatography as well as precipitation), further purification (e.g., ion-exchange, hydrophobic, and gel chromatography), and finally polishing (gel filtration, diafiltration, ultrafiltration) and techniques for virus inactivation (acid/base treatment, nanofiltration or ultraviolet-c (UVc)) [653, 655, 656]. The early stages within a purification strategy will aim to achieve both concentration and purification. The next step will be the major purification step. The number of steps included in "further purification and "polishing" will depend on the intended use of the protein, as they are mainly designed to reduce contaminants such as DNA, host cell protein, endotoxins, process chemicals, etc. The importance of the downstream process is underlined by the fact, that an estimated 60–80 % of the total production costs are attributed to purification [438, 439, 654].

9.1.9. Regulatory and Safety Issues

Pharmaceutical production processes are subject to strict regulations and regular inspections to ensure the high quality demands for medicines [439, 440, 657]. Guidelines for aspects relevant for the production process are summarized under cGMP and corresponding lists were released in the United States by the FDA [480] as well as by the EU [481]. There are some special concern with the use of mammalian cells for production of biopharmaceuticals, e.g., 1) risk of contamination by microbes, mycoplasma, or viruses, 2) the genetic stability of the host cell line, or 3) the consistency of the product (glycosylation pattern, etc.). The documents to be submitted to the authorities include detailed information concerning the product, the production process, product characterization including analytical methods, validation procedures, methods, and results of clinical trials. The efforts to fulfill these requirements are quite high and bind significant resources within the companies [439].

9.2. Tissue Engineering

In this chapter, an overview in the field of "red biotechnology" is presented. Red biotechnology comprises three major fields:

- Gene therapy
- Production of proteins, antibodies, and vaccines for diagnostics and therapy
- Tissue engineering

Gene therapy is a therapeutic approach based on the correction of a gene defect causing a disease. Different techniques exist for achieving this aim. In most cases, the wild-type gene is inserted into the genome by special methods replacing the mutant gene, which leads to the development of the disease. The most common vectors for the transport of the correct gene into the genome are viruses.

In the mid-eighties, several treatments with the genetically modified cells were reported. The first gene therapy approach was reported in 1990 on a young girl suffering from severe combined immunodeficiency (SCID). But the therapy did not work out, after a few months the procedure had to be repeated regularly.

A major drawback within this field emerged when it was evident that a young patient died after being treated by gene therapy [658]. The patient was suffering from a rare liver disease and was a volunteer in a gene therapy program. Similar incidences occurred in the year of 2000 within a group of boys after gene therapeutic treatment of SCID. The majority of the boys in this group developed leukemia. Since then, gene therapy is only broadly applied within science-fiction movies. Researchers working in this field went back a few steps to elucidate the devastating incidences [659].

Biological active compounds produced from genetically modified cell cultures have been in use for several years in the treatment of a whole range of diseases. In most cases, the active ingredients are proteins such as blood clotting factors (e.g., tissue plasminogen activator, t-PA), growth factors (e.g., erythropoitin, EPO), or monoclonal antibodies [660]. All these substances can be produced in animal cell cultures. These proteins can also be applied in diagnostic assays (e.g., ELISA). For more "simple" molecules such as non-glycosylated proteins, peptides and hormones, bacterial or yeast cells can be utilized for production.

9.2.1. Application of Tissue Engineering

Tissue engineering is a rather young and rapidly growing interdisciplinary research field which combines the principles of engineering, life, and clinical sciences (Fig. 38). The aim of this research field is the development of biological substitutes that restore, maintain, or improve tissue functions [661, 662]. Therefore, the knowledge of cellular interactions, molecular transport phenomena, interactions of cells with material surface, mechanical loading, and biochemical interventions is applied.

An official definition was presented at a conference of the National Science Foundation in 1988: "*... the application of principles and methods of engineering and life sciences toward fundamental understanding of structure–function relationship in normal and pathological mammalian tissues and the development of biological substitutes to restore, remain, or improve tissue function*".

Over the past two decades, encouraging results have been achieved. Methods and techniques of tissue engineering have already entered therapeutic practice, e.g., for the treatment of sports injuries and damage to cartilage. The main approach adopted in these cases is known as autologous chondrocyte transplantation (ACT). Cells isolated from cartilage tissue of the patient (autologous) are seeded onto a collagen matrix and cultivated until a three-dimensional tissue structure is generated. Then the construct can be implanted into the defect [663 – 665]. Also tissue-engineered skin is already used, e.g., for therapy of severely burned patients [666 – 669]. Researchers are attempting to engineer almost every human tissue or organ because the demand of tissue-engineered cells and organs is still growing because of the fact of organ shortage for transplantation. The creation of three-dimensional tissue constructs which can mimic all functions and metabolic activity like organs (e.g., liver [670] or pancreas [671]) is still a crucial challenge. The first tissue-engineered heart valves have been implanted to a patient and show promising results in function and mechanical stability [672, 673].

Figure 38. Disciplines involved in tissue engineering

Figure 39. Principle of tissue engineering

9.2.2. Principle of Tissue Engineering

The principle of tissue engineering can be demonstrated in the following way: First, cells have to be isolated. The cells are seeded to a matrix and are extracorporal cultivated in a suitable culture system or bioreactor in medium containing nutrients and growth factors. After cultivation, the resulting tissue is reimplanted into the patient (Fig. 39).

Tissue engineering is driven by the hopes of the patients of increased availability of transplantable organs, to ease their suffering, forestall imminent death, and enabling a better quality of life. Alongside these medical objectives, there are also huge economic issues at stake because treatment of tissue and organ damage or dysfunction often involves long hospitalization and thus is very expensive. In contrast to alternative approaches of xenogenic (from an-

other species) and allogenic (same species but another individual) organ transplant, tissue engineering involves transplanting cells from the body of the patient itself. This is the reason for which such great attention has been focused in the last few years on this new area of research. By growing artificial autologous tissue and organs in vitro, the risk of rejection by the immune system of the body can be avoided. Tissue engineering techniques can be used to generate replacement tissue for internal organs (liver, pancreas, heart, kidneys, lungs), sensory organs (eyes, ears, nose), the skeleton (bones and cartilage), the brain and nerves (in particular for the treatment of Alzheimer's disease and Parkinson's disease), or the skin (e.g., treatment of severe burns).

A closely related concept to tissue engineering is *regenerative medicine*. Here, the emphasis is placed on supporting the body's natural healing processes. The potential of stem cells is crucial for both fields.

9.2.3. Strategies

Tissue engineering can be performed by using one of the three approaches:

In vitro cultivation of autologous cells on organic, synthetic, or natural matrices
In vitro cultivation of autologous cells on xenogenic matrices
Iin vitro tissue generation from embryonic stem cells

Depending on the tissue of interest, either a close system (e.g., extracorporal device, artificial liver) or an open system based on a biodegradable polymer scaffold is developed. The autologous cells can be isolated tissue-specific primary cells or stem cells.

9.2.4. The Essentials

The essentials for tissue engineering are shown in Figure 40. For a successful generation of three-dimensional tissues, suitable cells have to be isolated and cultivated on a matrix in an appropriate medium containing all necessary growth and differentiation factors by using an optimized bioreactor system. During cultivation, the application of a mechanical load (e.g., strain, compression) is beneficial for the development of three-dimensional cell–cell contacts resulting in functional tissue [674 – 682].

Figure 40. The "essentials" for tissue engineering

9.2.5. Cells

For tissue engineering, either tissue-specific cells can be isolated and cultured or stem cells can be used for the directed differentiation to the desired tissue. Due to their potential for differentiation into several different tissue types, nowadays the use of stem cells is intensively discussed [683]. In numerous publications adult stem cells isolated from bone marrow (bone marrow stromal cells BMSC [684 – 686], fat tissue (adipose-derived stem cells adSC [687]), and peripheral blood or umbilical cord blood (both haematopoietic cells [688, 689]) are applied. The potential for differentiation into several different types of tissues is already approved. Mesenchymal stem cells (MSC) play a major role in modern tissue engineering [690, 691]. These cells are easy to isolate from bone marrow or fat tissue and their availability is not so limited compared with that of the small number of stem cells present in, e.g., peripheral blood (0.1–0.2 %). Treatment concept based on the use of autologous stem cells would eliminate problems of donor site scarcity, immune rejection and pathogen transfer.

9.2.6. Biomatrices

There has been also huge progress in the development of biomaterials for use in tissue-engineering applications [692, 693]. Research

has concentrated on the development and production of biocompatible and biodegradable materials [694 – 697]. Such biomaterials take over the task of the extracellular matrix (ECM), which naturally provides cells with a supportive framework of structural proteins, carbohydrates, and signaling molecules. The ideal scaffold has to mimic ECM features and would be made of a biomaterial that provides all the necessary signals for the cells to grow, differentiate and interact, forming the desired structure. Regardless that general properties and design features of the biomaterials for discussed purposes have been published in a numerous reviews [698 – 702], the subject still represents intensive scientific and practical interest. Besides natural occurring compounds or scaffolds, also synthetic biomaterials are reviewed in the literature [703 – 705]. Along with polysaccharide- and protein-based (e.g., hyaluronic acid, collagen) materials, also many synthetic polymers are used for tissue-engineering application (e.g., polylactic acid, polyglycolic acid, polyurethane, polyesters).

9.2.7. Bioreactors for Tissue Engineering

The design, control, and operation of bioreactors in technical and engineering disciplines are well-established. Their use in medical sciences requires an interdisciplinary approach aiming at the development of functional tissues. Therefore, frequently the application of mechanical loading is needed [706 – 709]. The loading can be disposed in different ways; for example, a longitudinal straining leads to the formation of ligaments or tendons; compression is applied when aiming at the development of, e.g., cartilage; pressure (perfusion) can be applied for bone tissue formation and pulsed bioreactors are used for blood vessel generation. In Figure 41, a selection of bioreactor schemes for tissue-engineering applications is presented. Unlike in conventional mammalian cell culture, where only a limited number of bioreactor types are used (e.g., T-flaks, roller bottles, spinner systems, stirred-tank reactors), in tissue engineering tailor-made bioreactors have to be developed and constructed for each specific tissue type, considering in particular the fluid dynamics which are realized by these different systems.

Figure 41. Selected bioreactor types for tissue engineering

Since human cells are anchorage-dependent, they must be attached to a matrix in the bioreactor during the cultivation. In a rotating-wall system, the cell-seeded matrices are cultured while the reactor wall is rotated, thus the cells float through the medium and are affected by microgravitylike conditions, and the mass-transfer rates are improved. Moreover, cell-seeded matrices can be cultured while hanging in spinner flasks, which results also in an improved mass transfer. Another possibility is the continuous pumping of the medium through a fixed bed with cells or the cells can be placed into a chamber where a mechanical stimulation (here compression) is applied.

9.2.8. Growing New from Old

The idea of organs one day being freely available "off the shelf" is still an aspiration today. The need is great, however, and patients are of course very eager to have "personalized" treatment from "organ designers" using tissue engineering. The most ambitious concepts involve applying a sort of "building-block" principle to the culture of each tissue or organ type: so-called precursor or stem cells would be used, whose potential for differentiation could be exploited through the use of appropriate growth or differentiation factors. Thanks to this method, one would "only" need the appropriate "ingredients": Further advantages of this approach are the fact that an organ or tissue replacement can be carried out at any time – in other words it can

be scheduled in advance. Regenerative medicine has great potential: according to a report in Time Magazine, over the next 10 to 20 years, tissue engineering will become one of the top careers and a new era in life sciences and medicine dawns. The potential applications are highly diverse but are to be found essentially in the treatment of cells and tissue which possess little or no capacity to repair themselves such as cartilage, heart muscle and nerve tissue.

The medicine of tomorrow will strive to develop personalized therapeutic procedures involving the patient in each treatment choice. There will be a move from a general "one-size-fits-all" approach to personalized treatment based on the principle of "one drug, one therapy, one patient". This will mean using a systems biology approach to fully restore the original healthy state of the patient. This dream could be realized thanks to the emerging technologies of regenerative medicine and tissue engineering.

Groups of cells and tissue generated by using tissue engineering can also serve as test systems which exhibit characteristics specific to a given organ. These can be used to test the effectiveness and duration of certain drugs or to study their mechanisms and metabolism, thus representing an alternative to animal experiments, and a rapid, broadly applicable and cost-effective way of screening pharmaceutically active substances.

Over the last ten years, there has been an explosion of research in tissue engineering, which shows the enormous importance attached to this technology. Within Europe, German researchers are playing a major role. Leading research is also being carried out by teams in France, Britain, Italy, and the Netherlands. Large numbers of small biotechnology companies are working in tissue engineering and more and more are being set up all the time.

In the 21st century, major scientific questions concern modern developments within the field of regenerative medicine, which includes tissue engineering, transplantation, prosthesis, as well as pharmacological interventions stimulating in situ tissue regeneration.

9.3. Biotechnology and Food

It is not presumptuous to claim that modern biotechnology has developed from traditional processes of food preparation. The production of alcoholic beverages, the coagulation of milk proteins, and the preservation of vegetable food by fermentation has already been familiar to most ancient civilizations. Thus, several microorganisms have a very long history of safe use in human food production. The main focus of this chapter is not on traditional fermentations but on recent developments in food biotechnology. Since this field is remarkably ambitious and complex, only some techniques of high industrial relevance are covered exemplarily. Genetic engineering of plants has yielded, for example, herbicide tolerant "RoundUp Ready" soy, *Bacillus thuringiensis* toxin expressing maize (Bt maize) and transgenic rice lines with an increased concentration of β-carotene in the endosperm ("golden rice"). Genetically engineered animals may produce milk with an altered protein profile, and modification of the hormone expression of fish imparts accelerated growth rates. A number of comprehensive reviews on food biotechnology are available [710].

9.3.1. Production of Food Additives by Cell Culture Systems

9.3.1.1. Amino Acids

L-Amino acids represent the largest group of food and feed additives produced by means of biotechnology [711]. Consequently, the literature published within the last decade is notably versatile. L-Glutamic acid ((*S*)-2-aminoglutaric acid, E 620) was the first amino acid produced biotechnologically on an industrial scale, and is still the leading amino acid by volume. More than 800 000 t/a of monosodium glutamate, which serves as a flavor enhancer ("umami taste"), are produced worldwide by cultivation of *Corynebacterium glutamicum* and related organisms. The production of L-glutamic acid may be enhanced by overexpression of the glutamate transporter gene (yhfK) [712], by use of streptomycin resistant *Brevibacterium lactofermentum* strains [713], and by optimization of the

culture conditions [714]. The second most important amino acid is L-lysine ((*S*)-2,6-diaminohexanoic acid), which is mainly used to supplement animal feed with this essential and often limiting amino acid. It is industrially produced by *C. glutamicum* or by *E. coli* species [711]. Efficient industrial producer strains have been developed by multiple rounds of mutagenesis. Defined L-lysine producing *C. glutamicum* mutants have been generated for example by modification of the enzyme aspartate kinase (lysC mutation) [715], attenuation of the transcription regulator tipA gene [716], and the introduction of a mutation (S361F) into the 6-phosphogluconate dehydrogenase gene (gnd) [717]. In the latter case, the modified strain was less sensitive to allosteric inhibition by intracellular metabolites than the wild-type strain. Product yields of up to 100 g/L are attainable within 24 h of cultivation with the recombinant production strains. A third amino acid, L-cysteine ((*R*)-2-amino-3-mercaptopropanoic acid), which is applied as a dough conditioner in the bakery industry, may be obtained from recombinant *E. coli* [718 – 720].

9.3.1.2. Organic Acids

Citric acid (2-hydroxy-1,2,3-propanetricarboxylic acid, E 330) is widely used to lower the pH of food (candy) and beverages (soft drinks, wine). Furthermore, it acts as an efficient chelator of prooxidative iron and copper ions. Various fungi and bacteria may be used for the biotechnological synthesis of citric acid starting from numerous substrates. The process has recently been comprehensively reviewed in [721]. *Aspergillus niger* grown as surface cultures on diluted molasses has been employed as early as in the 1920s, and still is the most popular production organism. Today, distillers' grains [722], palm oil mill effluents [723], or cassava starch factory wastes [724] may serve as cheap and abundantly available substrates. By optimization of the growth conditions (sufficient oxygen supply in submerged cultures; media deficient in manganese, copper, iron, and zinc ions; high glucose concentrations), and by selection of overproducing *A. niger* strains, yields of > 100 g/L are attainable [725]. The yeast *Yarrowia lipolytica* represents a future potential production organism. The strain *Y. lipolytica* 187/1 showed maximum synthesis rates when grown on raw agro-industrial fats as substrates [726], while Rymowicz and Cibis [727] selected the acetate-negative strain *Y. lipolytica* AWG-7, cultivated on glucose syrup, for citric acid production. As a second important organic acid, L-lactic acid ((*S*)-2-hydroxypropanoic acid, E 270), has been used from ancient times as a food preservative by lowering the pH during fermentation. More recently, lactic acid has gained increasing interest since the monomer is used for generation of the biodegradable food packing polymer "polylactic acid (PLA)". However, only few PLA-generating processes have been commercialized and the cost of PLA is still not able to compete with synthetic plastics [728, 729]. Apart from traditional lactic acid bacteria such as *Lactobacillus delbrueckii* [730] or *L. plantarum* [731], a wide range of further microorganisms, especially strains of *Rhizopus oryzae,* has been employed for the biosynthesis of L-lactic acid (for example [732, 733]). A current review on metabolic engineering approaches of lactic acid bacteria is available [734].

9.3.1.3. Vitamins

L-Ascorbic acid (vitamin C, E 300) is produced by a combination of chemical synthesis and enzymatic reaction steps. Known as "Reichstein process", the procedure was established already in the 1930s. The key biotransformation step, the oxidation of D-sorbitol to L-sorbose, is catalyzed by *Acetobacter suboxidans* [735]. Due to the worldwide use of L-ascorbic acid as vitamin in dietary supplements and as antioxidant in food and feed, the annual need sums up to 60 000 t [711]. Novel approaches use either recombinant microorganisms in one-step procedures [736] or *Azotobacter chroococcum* strains [737] for L-ascorbic acid production. For a review on biotechnological routes to vitamin C, see [738]. Further water-soluble vitamins, including riboflavin (vitamin B_2) and cyanocobalamin (vitamin B_{12}), are currently produced by microbial cell cultures. The chemical synthesis of the yellow-greenish-colored riboflavin has been largely replaced by biotechnological processes using either the overproducing fungus *Ashbya gossypii* [739] or mutant strains of *Bacillus subtilis*. The "generally recognized as safe" (GRAS)

organism *B. subtilis* is widely used in the food industry [725] and, for example, the mutant strain CJKB0002 produced 26.5 g/L riboflavin compared to 22.4 g/L obtained from the parent strain [740]. Detailed mechanistic studies on the riboflavin synthesis in *Ashbya gossypii* [739] and in the lactic acid bacterium *Lactococcus lactis ssp. cremoris* [741] have been published. Cyanocobalamin is derived from *Propionibacterium* or *Pseudomonas denitrificans* species [711]. Recently, a fermented milk product containing *Propionibacterium freudenreichii ssp. shermanii* B369 bacteria, capable of producing cyanocobalamin in situ, was patented [742]. Thus, a vitamin B_{12} enriched yogurt may be manufactured as a "nutraceutical" without external vitamin fortification. However, comparatively low world-wide annual production rates of 3000 t for vitamin B_2 and 10 t for vitamin B_{12} document the predominant use of theses vitamins in dietary supplements and in pharmaceuticals [711]. The main plant-derived carotenoid, β-carotene (E 160a), serves as provitamin A in the human diet. Since β-carotene additionally imparts an intense yellow-orange coloring, it is widely used as a natural food additive. The development of biotechnological processes for the production of β-carotene is mainly driven by the increasing demand of the food industry. Besides the extraction from plants (for example from lucerne), β-carotene is industrially obtained from the algae *Dunaliella salina* [743] or from the fungus *Blakeslea trispora* [744]. The carotenoid astaxanthin, which is used on a large scale in aquaculture for the coloring of salmonids and crustaceae, is formed by the yeast *Phaffia rhodozyma* [745].

9.3.1.4. Sweet Compounds

Palatinit (isomalt, E 953) is a non-cariogenic sugar substitute used in low-calory food, desserts, ice creams, and diabetic food. It is a white, crystalline, and non-hygroscopic substance with a sweetening power of roughly 0.45–0.60 compared to that of sucrose (1.0). In the first production step, sucrose is converted enzymatically (by action of a glycosyltransferase) into palatinose (isomaltulose, *O*-α-D-glucopyranosyl-(1–6)-D-fructofuranose) by immobilized cells of *Protaminobacter rubrum*. Subsequently, palatinose is reduced to palatinit, an equimolar mixture of the corresponding alcohols (1-*O*-α-D-glucopyranosyl-D-mannitol and 6-*O*-α-D-glucopyranosyl-D-sorbitol) by hydrogenation on a fixed-bed Ni catalyst. In the industrial process, it is advantageous to use immobilized non-viable cells of *P. rubrum* in a packed-bed reactor for the enzymatic step [746]. Apart from *P. rubrum*, immobilized cells of *Serratia plymuthica* [747], *Erwinia* sp. D12 [748], or *Klebsiella singaporensis* LX3T (isolated from soil) [749] have been used to convert sucrose into palatinose. In 2005, palatinose was approved according to the EU regulation (EC 258/97) concerning novel foods and novel food ingredients, and the GRAS registration was granted in 2006 by the US Food and Drug Administration (FDA). Recent inventions suggest a mixture of palatinose with cocoa powder for the preparation of instant beverages [750]. Further applications comprise the use of palatinose for the production of low-alcohol beer or beerlike soft drinks [751], and the preparation of fermented soybean milk [752].

In the industrial production of the sweetener aspartame (α-L-aspartyl-L-phenylalanine 1-methyl ester, E 951), the methyl ester of the "DF" dipeptide, both components are produced by biotechnological processes. L-Phenylalanine is usually manufactured by large-scale cultivation of the soil bacteria *Serratia marcescens* or *C. glutamicum*. Immobilized aspartase or alternatively intact cells of *E. coli* are used to synthesize L-aspartic acid starting from the precursors ammonia and fumarate [725]. Usually, amid formation is performed chemically although an enzymatic approach exists [753]. Thermolysine, immobilized on an agarose–aldehyd gel, is used as biocatalyst for the synthesis of enantiopure aspartame [754]. Thermolysine is a metallopeptidase with a zinc ion in its active site and four calcium ions, which stabilize the tertiary structure of the enzyme.

9.3.1.5. Sugar Alcohols

Sugar alcohols such as D-sorbitol (D-glucitol; E 420) and D-xylitol (E 967) have attracted the attention of the food and pharmaceutical industry because of their sweetening and non-cariogenic properties. Due to the fact that their metabolism

is insulin-independent, they are well suited for substituting sugar in diet schemes for diabetics. Since the biotechnological production of xylitol represents an economically attractive alternative to the industrialized chemical process, various process variants have been published. Somewhat less literature is available on sorbitol, which is mainly formed by cultures of *Zymomonas mobilis* [755, 756]. The synthesis of xylitol by *Candida guilliermondii* depends on several crucial process parameters, one of which is the concentration of phosphate buffer in the culture broth (optimum at 0.6 M) [757, 758]. In another approach, the D-xylitol production of the yeast *Debaryomyces hansenii* UFV-170 was monitored with respect to temperature and starting pH [759]. Various substrates, including for example hydrolysates of corn cobs [760] and sugarcane bagasse [761] have been used for the bioconversion of the pentose D-xylose to xylitol.

9.3.1.6. Microbial Saccharides

The most popular polymer currently produced by means of biotechnology is xanthan gum (E 415). Xanthan gum is a complex bacterial exopolysaccharide structurally closely related to cellulose. Today it is mainly produced by mutants of *Xanthomonas campestris* (40 000 t/a [711, 762]), a Gram-negative bacterium that is pathogenic to many crops. Due to its outstanding properties (high salt and pH tolerance, thermostability, and unusual rheological behavior), xanthan is predominantly used as a thickener in dressings and convenience food [763]. Sago starch has been suggested as an alternative carbon source instead of glucose [764]. Trehalose (α-D-glucopyranosyl-(1-1)-α-D-glucopyranose) is a nonreducing disaccharide that is thought to play a role as storage carbohydrate for many microorganisms. It may serve as an additive to improve the freeze stability of processed food. In 2000 and 2001, trehalose has gained the FDA GRAS and the EU novel food approval, respectively. Trehalose is obtainable inter alia from *Brevibacterium* [765], *Cellulosimicrobium cellulans* [766], or *Debaryomyces hansenii* strains. The latter two were cultivated under moderate saline stress for extracellular trehalose production [767]. Literature [768] reviews trehalose production (with a focus on the conversion of starch to trehalose) and potential applications in the food industry.

9.3.1.7. Conjugated Linoleic Acids (CLA)

Lactic acid bacteria play a prominent role in the traditional fermentation of food. One of the exceptional features of some lactobacilli is their ability to isomerize linoleic acid to different conjugated linoleic acid isomers (CLA). The *Z*9,*E*11- and *E*9,*E*11-octadecadienoic acid are assumed to possess beneficial physiological and anticarcinogenic properties [735]. *Lactobacillus plantarum* AKU 1009a formed up to 40 mg/mL CLA (33 % molar yield) in 108 h under optimized conditions from 12 % (w/v) linoleic acid as substrate [769]. Further lactobacilli capable of CLA production encompass for example *L. delbrueckii ssp. bulgaricus* [770] and *L. plantarum* JCM 1551 [771]. Castor oil proved to be an adequate substrate for CLA formation. Presumably, a two-step reaction mechanism, involving hydration of a double bond with subsequent elimination of water, is leading to different CLA isomers [772].

9.3.1.8. Lactulose

Lactulose acts as a prebiotic compound and thus may contribute to increased levels of "health-promoting" bacteria (bifidobacteria and/or lactobacilli) in the human intestinal tract [773]. The term "prebiotics" comprises a wide variety of oligosaccharides that are not digested in the stomach and in the small intestine. They naturally occur in garlic, asparagus, onion, and others. Apart from soybean oligosaccharides, a number of uncommon fructo-, galacto-, xylo-, and isomalto-oligomers are currently in use, especially in Japan [773]. The disaccharide lactulose (4-O-β-D-galactopyranosyl-D-fructose) is a non-naturally occurring compound with potential applications in infant milk formulations and foods [774]. Although lactulose is chiefly manufactured chemically using boric acid or aluminates as catalysts, a biotechnological route starting from lactose (as galactose donor) and fructose with permeabilized *Kluyveromyces lactis* yeast cells has been developed [775]. In

another approach, β-galactosidase from *Aspergillus oryzae* and a hyperthermostable β-glycosidase from *Pyrococcus furiosus* were used for the transgalactosylation of lactose in the presence of fructose [776]. Important food additives and food supplements produced by cell culture systems are summarized in Table 19.

9.3.2. Enzyme-Catalyzed Processes

The modification of starch and lipids as well as the production of cheese and fruit juices are prime examples of enzyme-catalyzed bioprocesses in the food industry. For economic reasons, the necessary enzymes are often employed as crude products or even as mixtures of enzymes with different properties. If required, the enzymes are purified by means of precipitation, ultrafiltration and/or fast protein liquid chromatography (FPLC). Common FPLC protocols comprise one ore more of the steps hydrophobic interaction chromatography (HIC), ion exchange chromatography (IEX), and size exclusion chromatography (SEC). Reusability and sometimes also stabilization may be achieved by immobilization of the biocatalyst on an inert carrier material.

9.3.2.1. Starch-Modifying Enzymes

Traditionally, the degradation of starch to maltodextrins and glucose/fructose syrups was performed by acid-catalyzed hydrolysis, using strong mineral acids such as hydrochloric or sulfuric acid. The harsh reaction conditions afforded a variable spectrum of unwanted by- and breakdown products. Therefore, the acid hydrolysis has been replaced more and more by enzymatic processes. Today, starch-converting enzymes comprise about 30 % of the enzyme market worldwide. Amongst the starch converting enzymes, α-amylase (EC 3.2.1.1, 1,4-α-D-glucan glucanohydrolase) holds the largest market share with major applications in the starch and bakery industries [777, 778]. α-Amylases may be derived from several plant materials, bacteria, yeasts, and fungi [779]. For commercial applications, mainly strains of *Bacillus amyloliquefaciens* and *Bacillus licheniformis* are employed as enzyme producers. α-Amylase attacks the α-(1-4)-links within the starch molecule (endoamylase), while the α-(1-4)-bonds near α-(1-6)-branches are resistant to hydrolysis. Thus, the end products of extensive α-amylase treatment are oligosaccharides of varying length with α-configuration and α-limit dextrins, which constitute branched oligosaccharides. Since α-amylase of *B. licheniformis* is remarkably thermostable (it remains active for several hours at temperatures of > 90 °C), its application in the industrial starch hydrolysis is highly efficient [780].

β-Amylases (EC 3.2.1.2; 1,4-α-D-glucan maltohydrolase) are present mainly in higher plants, but also in some microorganisms. Commercial products are available from malt, soy, and wheat. They hydrolyze α-(1-4)-glucosidic bonds, effecting successive removal of maltose units from the nonreducing end (exoamylase). In contrast to amylose, amylopectin is not completely hydrolyzed, as all reactions stop before branch points are reached (β-limit dextrin).

Glucoamylase (EC 3.2.1.3; 1,4-α-D-glucan glucohydrolase) is formed predominantly by fungi and yeasts (*Aspergillus*). It starts at the nonreducing end of α-(1-4)-D-glucans and successively liberates β-D-glucose units. The α-(1-6)-bonds in amylopectin are also cleaved, but around 30 times slower than the α-(1-4)-bonds. At higher concentrations, glucoamylase reforms all the glycosidic bonds that it hydrolyses. Thus, it condenses glucose, for example, to isomaltose (6-O-α-D-glucopyranosyl-D-glucose).

Debranching enzymes exclusively hydrolyze α-(1-6)-bonds in amylopectin, glycogen, and pullulan. Linear amylose fragments are formed from amylopectin. Pullulanase (EC 3.2.1.41; pullulan α-(1-6)-glucanohydrolase) hydrolyzes α-(1-6)-bonds in pullulan (a linear polymer of α-(1-6)-linked maltotriose units) and amylopectin, while isoamylase (EC 3.2.1.68) is only capable of the hydrolysis of the α-(1-6)-bonds in amylopectin. Pullulanases have been found in a variety of bacteria; industrially used is an enzyme derived from *Bacillus acidopullulyticus*.

Cyclodextrins are produced via an intramolecular transglycosylation reaction in which the enzyme cyclodextrin glycosyltransferase (EC 2.4.1.19; 1,4-α-D-glucan 4-α-D-(1,4-α-D-glucano)-transferase) cleaves the α-(1-4)-glycosidic bond and concomitantly links the reducing to the nonreducing end.

Table 19. Examples of food additives and food supplements produced by cell cultures

Product	Use	E number	Production organism
L-Glutamic acid	flavour enhancer	E 620	*Corynebacterium glutamicum*
L-Lysine	feed supplement	–	*C. glutamicum*
L-Cysteine	bread enhancer	E 920	*Escherichia coli*
Citric acid	acidity regulator	E 330	*Aspergillus niger*
L-Lactic acid	preservative	E 270	*Lactobacillus* ssp.
L-Ascorbic acid	vitamin C; antioxidant	E 300	*Acetobacter suboxidans*
Riboflavin	food coloring;vitamin B_2	E 101	*Bacillus subtilis*
Cyanocobalamin	vitamin B_{12}	–	*Propionibacterium* ssp.
β-Carotene	food coloring; provitamin A	E 160a	*Dunaliella salina, Blakeslea trispora*
Palatinit (Isomalt)	sugar substitute	E 953	*Protaminobacter rubrum*
Aspartame	sweetener	E 951	*Serratia marcescens, C. glutamicum*
D-Xylitol	sugar substitute	E 967	*Candida guilliermondii*
Xanthan	thickener; stabilizer	E 415	*Xanthomonas campestris*
Trehalose	cryoprotectant; stabilizer	–	*Brevibacterium* ssp.
Conjugated linoleic acids (CLA)	active ingredient of functional food	–	*Lactobacillus* ssp.
Lactulose	prebiotic	–	*Kluyveromyces lactis*

Syrups high in fructose level (42–44%, high-fructose corn syrups, HFCS) are obtained from glucose solutions by action of the enzyme xylose (glucose) isomerase (EC 5.3.1.5, D-xylose ketol isomerase) [725]. Technical enzymes are derived for example from *Streptomyces, Actinoplanes, Arthrobacter,* or *Bacillus* cultures. The large-scale isomerization of glucose is performed with immobilized enzymes, and product yields of up to 22 tons of isosugars per kilogram of catalyst are obtained. Fructose concentrations of about 90 % are accessible via a subsequent chromatographic purification step. An excellent survey of enzymes involved in the industrial processing of starch is presented in [781]; and the most important starch converting enzymes are summarized in Table 20.

9.3.2.2. Lipases

Lipases (EC 3.1.1.3, triacylglycerol acylhydrolase) are valued biocatalysts with numerous applications in food biotechnology. Many representatives of this enzyme class are highly stable in organic solvents, show broad substrate specificity, and high regio- and/or stereoselectivity [782]. Main fields of application include the rational design of lipids with specific structures ("functional oils and fats" [783]), and the production of volatile fatty acids and flavor esters ("natural food flavorings"). Volatile fatty acids are the so-called "character impact" flavor compounds of various types of cheese, while numerous flavor esters are responsible for fruity aroma impressions [784]. Industrial high-level production of lipases requires not only the efficient overexpression of the corresponding genes, but also a detailed understanding of the mechanisms governing the folding and secretion of the proteins [785]. Immobilized lipases from the yeast *Candida rugosa* are traditionally popular, as a wide core in the catalytic centre allows for acceptance of various fatty acids for *trans*-esterification or synthesis of mono- and diacylglycerides, for example, [786]. Especially *C. antarctica* lipase B features outstanding properties such as high thermostability, *sn*-2 recognition in hydrolysis of triacylglycerides, and selectivity towards *(E)*-fatty acids. A review on applications of the lipases A and B from *Candida antarctica* was published recently [787]. Several strains of another member of the *Candida* family, *Yarrowia (Candida) lipolytica*, were screened for lipase secretion. The highest lipase activity produced on rapeseed oil as sole carbon and energy source was found to be 2760 U/mL for *Y. lipolytica* 704 [726]. When cultured in a 2000 L bioreactor, the lipase activity reached 1100 U/mL after 53 h [788]. Lipases with novel catalytic properties are produced for example by the basidiomycetous fungus *Pleurotus sapidus*. An extracellular enzyme of the type B carboxylesterase/lipase family efficiently hydrolysed xanthophyll esters [789].

9.3.2.3. Pectin-Degrading Enzymes

Pectin is a complex polysaccharide (α-D-(1-4)-polygalacturonic acid, esterified with methanol in varying degree) that represents an essential

Table 20. Starch-converting enzymes

Enzyme	Enzyme number	Producer organism	Specificity
α-Amylase	EC 3.2.1.1	*Bacillus licheniformis*	*endo*-α-(1-4)
β-Amylase	EC 3.2.1.2	malt, soy, wheat	*exo*-α-(1-4)
Glucoamylase	EC 3.2.1.3	*Aspergillus* ssp.	*exo*-α-(1-4); exo-α-(1-6)
Pullulanase	EC 3.2.1.41	*Bacillus acidopullulyticus*	*endo*-α-(1-6)
Cyclodextrin glycosyltransferase	EC 2.4.1.19	*Bacillus macerans*	intramolecular transglycosylation
Xylose isomerase	EC 5.3.1.5	*Streptomyces* ssp.	isomerization of glucose to fructose

part of plant cell walls. The group of pectinolytic enzymes comprises pectinases (polygalacturonases), lyases, and pectin esterases. A total market share of 25 % of the global sales of food enzymes is currently attained by this enzyme family [790]. To improve the yields in fruit and vegetable juice production, and to obtain clear and concentrated juices, especially pectinases from the mold *Aspergillus niger* are employed [791, 792]. For example, the efficiency of kiwi juice production was increased $> 10\,\%$ by addition of 40 mg/L pectinase for 150 min [793], and the yield of loquat juice was 16 % higher when 160 mg/L pectinase were added for 4 h [794]. Under these conditions, the loss of vitamin C was low and the juice was clarified. Endo- and exopectinases (EC 3.2.1.15, endopolygalacturonase; EC 3.2.1.67, exopolygalacturonase) depolymerize the pectin chain by hydrolytic cleavage of the glycosidic α-(1-4)-bonds.

Usually, pectinases are combined with hemicellulases (mixture of cell-wall-degrading enzymes) and cellulases (EC 3.2.1.4) to improve fruit liquefication, leading to high-quality juices in terms of oxidation, aroma levels, and stability [795]. As an auxiliary enzyme, α-L-arabinofuranosidase (EC 3.2.1.55), was suggested for applications in the wine industry and for clarification of fruit juices [796]. Pectin lyase (EC 4.2.2.10) and pectate lyase (EC 4.2.2.2) catalyse the eliminative cleavage of pectin and pectate, respectively, to oligosaccharides with 4-deoxy-α-D-gluc-4-enuronosyl groups at their nonreducing ends. Potential production organisms include *Erwinia* species as well as a number of phytopathogenic fungi. Pectin esterases (EC 3.1.1.11) catalyze the hydrolytic cleavage of the methyl ester group. These enzymes generally exhibit a high specificity for pectin substrates.

9.3.2.4. Chymosin (Aspartic Protease)

Chymosin (EC 3.4.23.4) is a key enzyme with peptidolytic activity used in the production of cheese. The casein fraction of milk protein is coagulated by hydrolysis of κ-casein between Phe_{105} und Met_{106} to form para-κ-casein and a glycopeptide (κ-casein glycomacropeptide). From a mechanistic point of view, chymosin belongs to the class of aspartate peptidases, which are characterized by the presence of two aspartic acid residues in the catalytic center.

Since recombinant chymosin does not exhibit unwanted side activities and is not contaminated with microorganisms possibly causing quality problems, it replaces rennin from the stomachs of calves (abomasus) to an increasing degree. The gene encoding chymosin has been cloned into different microorganisms, and the properties of the recombinant enzymes expressed in the yeasts *Kluyveromyces lactis* and *Pichia pastoris* have been compared [797]. Since *K. lactis* is regarded as a safe organism traditionally used in food processing, it is of outstanding importance in the biotechnological production of chymosin on an industrial scale [798]. The technological characteristics of various enzymes from genetically modified organisms were nearly identical to those of natural rennin, and only slight differences in the coagulation time and curd firmness were observed [799]. Chymosin obtained from transgenic sheep milk and the recombinant protein expressed by *K. lactis* differed only in their action on low-molecular-weight substrates, but not in enzymatic activity on protein substrates [800]. Recently, extracellular acid peptidases from *Rhizopus oryzae* have been suggested as rennin substitutes in cheese manufacturing [801, 802].

9.4. Biotechnology and Health

9.4.1. Individualized Medicine

Single nucleotide polymorphisms (SNPs, a single base is exchanged by an alternate) are the most common form of genetic variant in the human genome, occurring on average 1 per 1000 base pairs. Since the influence of SNPs on medical therapy or diet is better understood, the SNP diagnostic is coming in the focus of interest. One important goal of genome research is studying genetic variance among individuals to improve the knowledge and treatment of disease and to identify the variations in our genes that influence the risk of an individual of becoming ill. Because inherited differences influence most common diseases and many drug responses, the understanding of existing genetic variations in the human population is a promising approach in the development of tailor-made therapeutics. Eighty percent of the individual variations are SNPs, which have a direct impact of gene regulation or of a protein product of a gene. In cases where one SNP is sufficient to cause disease it is possible to analyze the causal change and to improve our understanding of disease [803 – 806]. The hope is that a complete human SNP map will increase the efficiency of drug development and medical treatment of disease. Many genotyping platforms have been developed to detect many SNPs at once in a efficient, cost-effective manner including microarrays by the use of allel-specific oligonucleotides containing the variable base. Large-scale SNP genotyping should lead to a fully understanding of the genetic architecture of common traits underlying disease, drug or diet response. For example, microarray experiments could help to define the ideal dose of a drug and quantify the impact of this dose on human health. Since these are the most personally data we know, the access to these data must be protected so it is not misused by employers or insurers. The goal of this analysis is to relate SNP variation to disease or diet.

9.4.2. Clinical Diagnosis as Indicated in Genetic Anomalies in Cancer

Solid tumors often show alterations in the genome that lead to changes in DNA sequences and copy number. These changes can be detected and mapped by using comparative genomic hybridization (CGH). CGH is a molecular cytogenetic method of screening for genetic alterations. These changes are classified as DNA gains or losses and show a characteristic pattern that includes mutations at chromosomal level. In the past few years, microarray-based formats for CGH have been developed made from large genomic clones and cDNAs. These arrays provide many advantages over conventional CGH, including higher resolution, direct mapping of changes to the genome sequence, and high throughput. Together with the analysis of complex differences in gene expression between normal and cancer cells, these data provide insight into malignancy and reveal genes that may be useful as diagnostic or prognostic markers. One problem performing cancer diagnosis using gene expression profiles from microarray analysis considers the heterogeneity of a tumor. Samples taken from different locations in the tumors are dramatically different. Therefore, biological classification on the basis of random sample analysis leads to poor reproducibility and may not be adequate [807 – 809].

9.4.3. Pharmaceutical Development

Drug biotransformation in man and animals can lead to a modulation of pharmacodynamic effects, drug elimination, but also drug toxicity. Knowledge of drug biotransformation pathways at early stages of drug development could considerably speed up drug development [810 – 813] and increase the safety of drug development in the pharmaceutical industry. Each year, more than 668 000 animals are used in toxicological drug research in Europe. Animal models suffer from serious shortcomings regarding the prediction for a human situation as significant species differences in enzyme expression exist between man and animals. Specifically, enzyme induction experiments are frequently misleading. 10–20 % of all new drugs are required to return into preclinical development trials after first clinical tests because of unforeseen metabolite patterns, whose toxicological relevance is unclear or untested.

Classical animal-testing strategies are time-consuming and therefore rather expensive in

Figure 42. Human liver cells

view of a delayed market penetration and return of investment. The relevance of a strict control of development time is immediately explicable by the fact that preclinical development of a novel drug can total up to several hundred million Euros. In spite of this, modern cell-culture technology has progressed to the extent that it is now possible to culture primary human cells under conditions that maintain differentiated functions to perform drug biotransformation and enzyme induction studies with great reliability in individual laboratories. Human liver cells are at present the preferred target for drug studies as the use of such cells avoids species extrapolation problems (Figs. 42 and 43).

Another significant breakthrough in pharmaceutical drug metabolism research was that these models could be sufficiently automated to enter into the field of accelerated screening as a significant initiation step towards high-throughput screening. Industrial strategies are aiming at integrating pharmacokinetics and toxicology into the early phases of drug compound selection to save time, cost, and effort in drug development. Therefore, the cell cultures and the chip technology were brought together by the pharmaceutical industry for preclinical drug research. Induction phenomena could be correlated with microarray chips containing all known genes involved in drug biotransformation. This information is used to describe the culture models used in this study and to develop the tools to fingerprint interactions of inducing agents with drugs. The use of microarray technology in the field of drug discovery and development provide four significant advantages:

Figure 43. Bioreactor systems for in vitro testing

– Gene expression in response to drug treatments
– Gene expression in model systems
– Gene expression patterns in disease
– Gene expression patters in pathogens (host–pathogen interaction)

9.4.4. Define Molecular Mechanisms of Toxicity

DNA microarrays can be used to determine the relative safety of natural or synthetic chemicals to which humans are exposed. Lots of diseases are influenced by environmental factors, for example, chemicals, radiation, drugs, nutrition, viruses, carcinogens, reproductive toxins, neurotoxins, and immunotoxins [814 – 819]. Although most of these chemicals are harmless, it is important to identify potentially hazardous substances. In the past, toxicological assays have used rodent, required high doses, were expansive, and take years to complete. Unfortunately, the information gained from established life animal models such as rodent to investigate enzyme induction and toxicity cannot really lead to correct assumptions of hazards to humans with respect to species extrapolation. The shortcoming with respect to predictivity of animal models for human drug biotransformation and toxicity is based upon a well accepted species difference in enzyme expression between man and animals. Nevertheless, at present animal models in drug metabolism and toxicology are still legally required in all European countries for a variety of reasons and legislative bodies are still hesitative to recommend specific human liver cell based tests. In spite of this, modern cell-culture technology has progressed to the extent that it is now possible to culture primary human liver cells under conditions that maintain differentiated functions to perform drug biotransformation and enzyme induction studies with great reliability in individual laboratories. These developments have not yet found entry into legal recommendations as no prevalidation of such models on a European scale has been achieved so far. The widespread use of such alternative models to animal investigations is being hampered both by insufficient prevalidation and by further improvements still required in the field of automation. It would be a significant breakthrough in toxicology research if these models could be sufficiently automated to enter into the field of accelerated screening as a significant initiation step towards high-throughput screening. Microarrays are powerful tools for investigating the mechanism of toxicity (Fig. 44). A microarray chip for cytochrome P450s and Phase II enzymes can be used to evaluate the liver culture models [820].

9.4.5. Detection of Genetically Modified Organisms

The use of genetically modified organisms (GMOs) in food industry has been rising exponentially over the past years. In the space of time from 1996 to 2003, global area of transgenic crops increased 40-fold, from 1.7×10^6 hectares in 1996 to 67.7×10^6 hectares in 2003, with a dominant trait of herbicide tolerance, followed by insect resistance (www.isaaa.org, International Service for the Acquisition of Agribiotech Applications). A GMO is "an organism, with the exception of human beings, in which the genetic material has been altered in a way that does not occur naturally by mating and/or natural recombination" [821]. Microarrays are a useful tool for GMO detection and the application of array techniques to GMO detection implies the capability of sensitivity and standardization of the assay. Today, commercialized arrays often do not fulfill these requirements, in spite of a few promising attempts initialized by biotechnical companies and research projects. Nevertheless, microarrays are already being used in GMO analysis but well established quantitative real time PCR techniques are state of the art. GMO detection becomes increasingly important because by-products of these organisms could end up in the food chain and affect human health.

10. Concluding Remarks

As it has been demonstrated in the previous chapters, biotechnology offers manifold possibilities in the production of different products and in medical applications. It can be used for better food, better health, and a cleaner environment. However, in the area of production of fine and bulk chemicals, biotechnology has still to

Figure 44. Investigation of toxicity through a combined cell-culture and microarray analysis

compete with the chemical industry. The chemical industry owes its success to the principle of unit construction: from simple basic substances, like ethylene, carbon monoxide or hydrogen, more complex precursors can be produced under controlled conditions by chemical reactions; because of the variety of combination options, the latter can in turn be converted into inconceivable quantities of derivatives and end products. Chemistry learned how to produce chemically pure basic substances from oil that are simple to handle and exactly defined; this is performed highly efficiently in refineries. This was the key to its success. Without exact knowledge of this functional principle, the triumphant success of plastics would have been just as impossible as the production of thousands of other chemical products that today make our lives safe and comfortable. This principle can also be applied to the so-called 'biorefinery' which has similar potential and could thus provide a further argument for the concept of material application of renewable resources and biotechnology. However, a technically viable separation procedure that would permit the separate use or further processing of all the primary products (such as cellulose, hemicellulose, and lignin) is still in its infancy. The main focus is on glucose, which can be derived by microbial or chemical methods from cellulose, since a wide range of biotechnological and chemical products can be obtained from glucose. The potential for the microbial conversion of glucose-based substances is huge and the reactions are advantageous from the viewpoint of energy. It is necessary to link the degradation processes to bulk chemicals via glucose as closely as possible to the synthesis processes of further derivatives.

Microorganisms still have a great potential for inducing new or novel enzyme systems capable of converting foreign substrates. It is possible to obtain and cultivate microorganisms that can survive or grow in extraordinary environments, e.g., psychrophilic, thermophilic, acidophilic, and alkaliphilic microorganisms. These microorganisms are capable of producing unique enzymes stable to heat, alkali, and acid. In addition, techniques for cultivation and enzyme purification, and gene and enzyme technology have made great advances and are still under development. Certainly biotechnological process development must be founded on a broader genomic basis. Ten years ago, only a handful of microorganisms with a completely sequenced genome existed, today there are several hundreds. Hitherto priority was given to sequencing pathogenic microorganisms, but it is now high time to sequence microorganisms that are relevant to industry. Taking all of these into consideration, there must be far more ways than one can imagine in using biotechnology for our daily life.

1. Introduction

Bismuth [*7440-69-9*], Bi, A_r 208.980, belongs to the fifth main group of the periodic table. Its chemical behavior is similar to that of the other group VB elements arsenic and antimony.

The electron configuration is [Xe] $4f^{14}$ $5d^{10}$ $6s^2$ $6p^3$. Only one stable isotope, ^{209}Bi, is known, but there are several unstable isotopes (^{199}Bi –^{215}Bi). Isotopes with mass number > 210 are found in the natural decay chains of radioactive elements. Isotopes with mass number $\leqq 208$ have been formed in nuclear transformations.

Bismuth is used as an alloying component in fusible alloys, but no commercial use of pure bismuth metal is known. Consumption seems to be declining; world production is only about 4000 t/a.

History. The name of the metal is to be found in all western languages. It is probably of Germanic origin and was mentioned first by ALBERTUS MAGNUS (1193 – 1280). Around 1450 BASILIUS VALENTINUS calls it *bismutum,* and PARACELSUS (1493 – 1541) named the metal *wismut.* GEORGUS AGRICOLA thought it to be a special kind of lead and describes the winning of *plumbum cinerum.* In 1739, POTT finally distinguished pure bismuth from other metals. Bismuth was known as a low-melting alloying element in the 16th and 17th centuries, and it was also used in the form of the subnitrate – in cosmetics and medicine. Industrial production be-

gan around 1830 in Saxony and increased after the first bismuth ores were shipped to Europe in 1867. The discovery of fusible alloys caused production to increase in the 1930s [1–4].

2. Properties [1–6]

Physical Properties. Bismuth is a heavy, lustrous, silver-white metal with a slight pink cast. If solidification is slow, large brittle crystals form. For a metal, bismuth has some unusual properties:

1) Like germanium and gallium, its volume increases on solidification. The increase is 3.32 %.
2) Bismuth is the most diamagnetic metal. Its specific susceptibility is -16×10^{-9} m^3/kg at 293 K.
3) Only liquid mercury has a lower thermal conductivity.
4) The electrical resistance of solid bismuth is greater than that of liquid bismuth. Superconductivity has not been detected. The increase in resistivity in a magnetic field (the Hall effect) is the largest of all metals.
5) Bismuth alloys show large thermoelectric effects.
6) With the exception of beryllium, bismuth has the lowest absorption cross section for thermal neutrons.

Thermal expansion, compressibility, heat conduction, self-diffusion, electrical resistivity, and mass susceptibility depend on crystal orientation [8].

Chemical Properties. Bismuth is not very reactive; generally, it is less reactive than lead and more reactive than silver. It shows annealing colors when heated but otherwise does not oxidize in dry air. Liquid bismuth is covered by an oxide film of Bi_2O_3 that protects it from further oxidation. At 817 – 821 °C the oxide melts, and then the metal oxidizes rapidly. Therefore it is possible to separate bismuth from the noble metals by cupellation. Moisture is slightly oxidizing at high temperatures. Other possible oxides are Bi_2O_4 and Bi_2O_5. In most compounds, bismuth has a +3 oxidation state, although in some compounds, such as Bi_2O_5, bismuth pentahalides, and a number of organobismuth compounds, it has oxidation state +5. Stable compounds with selenium and tellurium have interesting semiconductivity and thermoelectric properties (→ Thermoelectricity). Bismuth has a standard electrode potential of +0.28 V, placing it between antimony and copper in the electrochemical series. It can be separated from lead by electrolysis [2].

3. Occurrence [2], [3]

Bismuth ranks 64th in abundance in the earth's crust; like antimony and cadmium, its abundance is estimated to be 0.17 to 0.2 ppm. Most bismuth sulfides occur associated with lead, copper, and silver. A few deposits in which bismuth is a major mineral are also known. The most important pure bismuth minerals are native bismuth and bismuth glance, Bi_2S_3. Other bismuth minerals are bismite, Bi_2O_3; bismuth ocher, $Bi_2O_3 \cdot 3\,H_2O$; and bismutite and bismutosphaerite, $Bi_2(O_2/CO_3)$.

Deposits from magmatic granite nearly always contain bismuth in low concentration. Bismuth is mainly found surrounding intrusive rocks, thus it is perimagmatic. Together with complex minerals of silver, copper, and lead, it can end up in deposits far from ingeneous bodies. If the other elements are carried further, the bismuth ocher left may be worth working.

Significant European deposits are situated in Spain and Saxony (Germany). In China bismuth occurs together with tungsten, molybdenum, and tin ores, which may be dressed up to 60 – 63 % Bi. Bismuth minerals are found together with tungsten ores in South Korea. Important USSR deposits are in Adrasman, Tajikistan SSR. The most important bismuth deposits are in South America. The Cu, Pb, and Zn concentrates from Peru (Junin and Oroya) contain bismuth; in Bolivia, bismuth is found together with tin and sometimes with tungsten. Mines are found in Tasua and Chorolque, Department Potosí, and Caracoles, Cimsa Cruz Cordillere, where oxide and sulfide concentrates with 35 – 45 % Bi are produced.

4. Production

Bismuth is produced in small amounts from so-called bismuth ores or concentrates. The largest amounts are recovered as byproducts from lead and copper production, mostly during processing complex copper concentrates. Bismuth is also won from molybdenum, tungsten, and tin concentrates.

4.1. Crude Bismuth from Bismuth-Rich Mixed Concentrates

Only in rare cases are as-mined ores rich enough to be treated directly to produce metal. Usually the ores have to be enriched before processing. Because of the large variety of ore compositions there is no standard procedure for upgrading. A special process has to be developed for each deposit: mechanical enrichment and flotation are usually the preferred methods. Often these methods do not produce the desired results, and the bismuth concentrates must be enriched further, either by leaching or by volatilization, or some combination of both.

For the selective separation of bismuth from complex nonferrous metal concentrates that contain up to several percent bismuth, leaching with hydrochloric acid has proved effective:

$$Bi_2S_3 + 6\,HCl \longrightarrow 2\,BiCl_3 + 3\,H_2S$$

If weak acid is used, the reaction must be supported with H_2O_2. The bismuth is precipitated by hydrolysis on dilution or partial neutralization,

$$BiCl_3 + H_2O \longrightarrow Bi(OH)Cl_2 + HCl$$

$$Bi(OH)Cl_2 \longrightarrow BiOCl + HCl$$

or by cementation with iron turnings,

$$2\,BiCl_3 + 3\,Fe \longrightarrow 3\,FeCl_2 + 2\,Bi$$

Neither procedure leads to a pure precipitate. The hydrolysis precipitates slightly soluble chlorides along with the bismuth compound. These chlorides can be precipitated only partially in advance. The cementation also precipitates the more noble metals. Such precipitates are usually smelted with soda or Na_2S to separate bismuth metal from copper and lead, which go into a matte low in bismuth.

Processing of Complex Molybdenum – Bismuth Preconcentrates. The bismuth in a preconcentrate containing (wt %) 4.8 % Bi, 14.5 % Mo, 17.9 % Fe, 8.0 % Pb, 2.5 % Cu, and 7.4 % SiO_2 can be dissolved with concentrated hydrochloric acid; molybdenum does not dissolve. The dissolved bismuth is then cemented with iron turnings.

	Composition, wt%		
	Mo	Bi	Cu
Concentrates before leaching	14.5	4.8	2.5
Concentrates after leaching	16.3	0.02	–*
Cementate	<0.1	86 – 95	<0.1

* Not usually given

The enriched product is refined. The bismuth-free molybdenum preconcentrates may be upgraded further by flotation [9]. The flow diagram of this process is shown in Figure 1. The Molybdenite Corporation of Canada floats bismuth-containing molybdenum ores: 70 – 80 % of the Bi and 93 – 95 % of the Mo are recovered. This process produces a highly enriched Mo – Bi concentrate and an Mo concentrate (Table 1). In the first stage the Mo – Bi concentrate is leached with hydrochloric acid at 90 – 100 °C and finally with nitric acid. BiOCl precipitates from the bismuth-containing solution upon dilution to pH 2 – 3. Silver and lead chlorides also precipitate. Copper may be cemented afterwards with iron scrap. The BiOCl can be smelted with coal, caustic soda, and sodium sulfate at 820 °C. The copper and iron go mostly into the slag. The crude bismuth has to be refined further [10].

Figure 1. Hydrometallurgical separation of bismuth from Mo–Bi preconcentrate [9]

Processing of Sulfidic Copper – Bismuth Concentrates. The recovery of crude bismuth from sulfidic Cu – Bi concentrates is best illustrated by two examples.

The bismuth can be dissolved selectively with HCl in the presence of an oxidizing agent and precipitated as BiOCl by hydrolysis on neutralization of the solution. Figure 2 shows the flow diagram, and Table 2 shows the distribution of elements in the intermediate products. The wash water is recycled, which increases the recovery of Cu, Bi, and Pb. Altogether 95 % of the bismuth (and ≈ 1 % of the copper) is found in the BiOCl precipitate, and 98 % of the copper (and ≈ 4 % of the bismuth) is found with the copper concentrate and cement copper.

Figure 2. Hydrometallurgical separation of Bi from Cu–Bi concentrates [11]

The Cu – B concentrate is leached first with hydrochloric acid (90 – 100 °C) and then with nitric acid. BiOCl precipitates from the solution after dilution to a pH of 2 – 3. Silver and lead chlorides coprecipitate. Copper may be cemented afterwards with iron scrap [11].

Bismuth – copper concentrates are smelted in Telamayu, Bolivia, under reducing conditions after addition of soda to produce crude bismuth (> 92 % Bi), a lean alkaline copper matte (< 10 % Cu, < 0.3 % Bi, < 20 % Na), and a slag waste. The soda makes the slag low melting (< 1000 °C) and keeps the Bi content of the

Effluents	–	$\ll 1$	–	–	–

∗ Percentage of the initial concentrations in the Cu–Bi concentrate. These initial concentrations are 1.7 % Bi, 10.8 % Cu, 8.0 % Pb, and 0.34 % Ag, also present are 26.0 % Fe, 29.4 % S, 12.0 % SiO_2, and 2.8 % Zn

copper matte as low as possible. The flow sheet is shown in Figure 3. The crude bismuth is refined by conventional pyrometallurgical methods, the pre-refining in Bolivia, the final refining in Belgium [12].

4.2. Crude Bismuth from Lead Concentrates

Lead concentrates can contain significant quantities of bismuth. The average bismuth contents, g/t, are given below for several such concentrates [2]:

Kassandra, Greece	1800 – 2400
La Oroya, Peru	2300
Trepča, Yugoslavia	1600
Saxberget, Sweden	1100 – 1200
Milpo, Peru	1050
Aouli, Morocco	900
Atacocha, Peru	850
Raura, Peru	300 – 500
Bathurst, New Brunswick	450
Kimberley, British Columbia	350
Renström, Sweden	350
Garpenberg, Sweden	140 – 240
Rammelsberg, Germany	130 – 150

Lead production is usually carried out in two steps: (1) sintering and (2) reduction in a blast furnace (→ Lead). During this process the bismuth follows the lead without major losses, despite the volatility of bismuth. (See Table 3.) In any case, the flue dusts are usually recycled. The loss of bismuth in the slag is low, since bismuth is reduced before lead [14].

Table 3. Bismuth contents and distribution during conventional lead smelting [13]

Substance	Bi content, wt%	Bi distribution, %
Sinter roasting input		
Lead concentrates	0.03	66.3
Lead flue dusts	0.06	13.9
Copper flue dusts	0.07	15.1
Sinter roasting output		
Sinter	0.04	97.5
Flue dust	0.08	2.5
Blast furnace input		
Sinter	0.04	75.0
Drosses	0.07	14.4
Pb–Ag residue	0.02	3.1
Recycled slag	0.08	5.9
Blast furnace output		
Pig lead	0.08	77.3
Flue dust	0.04	12.8
Slag	0.001	1.1

Usually, bismuth is only a trace element throughout lead processing: only during lead refining is it enriched up to a few percent. The clean separation of bismuth from lead and the other elements present cannot be done by pyrometallurgical or electrolytic refining. Bismuth has less tendency than lead to form oxides, sulfides, or halides. Therefore, normal pyrometallurgical refining is not possible. Also, it is less electropositive:

$Sn^{2+} + 2e^- \longrightarrow Sn(s)$	-0.14 V
$Pb^{2+} + 2e^- \longrightarrow Pb(s)$	-0.13 V
$Sb^{3+} + 3e^- \longrightarrow Sb(s)$	$+0.2$ V
$Bi^{3+} + 3e^- \longrightarrow Bi(s)$	$+0.28$ V
$As^{3+} + 3e^- \longrightarrow As(s)$	$+0.3$ V
$Cu^{2+} + 2e^- \longrightarrow Cu(s)$	$+0.345$ V

Electrolytic refining can separate lead and bismuth, but Sb, As, Bi, and Cu remain together.

Figure 3. Processing of Bi–Cu concentrates in Telamayu, Bolivia [12]

4.2.1. Pyrometallurgical Separation of Bismuth from Metallic Lead

One method has been found to separate bismuth from lead: precipitation of the intermetallic compound $CaMg_2Bi_2$. The $CaMg_2Bi_2$ forms after addition of calcium–magnesium alloy to bismuth-containing lead melt (Kroll–Betterton process). The calcium and magnesium are added at 420 °C to the lead bath. The temperature is allowed to fall at a rate of 20 K/h until it is close to the melting point (330 °C). Then the intermetallic compounds rich in bismuth solidify, and, having a lower density than lead, float to the top, where they can be removed in the dross by skimming. The simultaneous solubilities of Ca, Bi, and Mg in lead close to its melting point can be calculated from the solubility product [15].

$$[\text{Mg,wt }\%]^2_{\text{Pb}} \cdot [\text{Ca, wt }\%]_{\text{Pb}} \cdot [\text{Bi,wt }\%]^2_{\text{Pb}} = 4.3 \times 10^{-8}$$

Figure 4 shows these equilibrium solubilities of bismuth in the lead corner of the Pb–Ca–Mg system. In practice, the bismuth concentrations in refined lead are slightly higher than the calculated values: usually ≈ 0.01 wt %. This is shown in Table 4 for two reported cases. The final bismuth concentration can be reduced below 0.01 % if antimony is added to a melt already treated with Ca and Mg [18].

The Ca–Mg consumption can be calculated. Because the residual concentrations of Ca and Mg are greater for lower bismuth contents, the specific consumption is much greater for low Bi contents, as can be seen in Table 5 [16], [17].

Table 5. Specific Ca and Mg consumptions for Bi removal from lead melts

$[Bi]_{Pb}$, wt %		Specific consumption, kg metal per kg Bi content	
before	after	Ca	Mg
0.05	0.009	1.06	3.5 calculated
0.09	0.009	0.62	2.05 calculated [16]
0.18	0.009	0.36	1.06 calculated [16]
0.2	0.020	0.25	0.60 ∗
0.68	0.014	0.15	0.39 [17]

∗ Calculated from data in *Ullmann,* 3rd ed., vol. 18, p. 635

Earlier, a mixture of K and Mg was used to separate the bismuth (Jollivet-Penarroya process), but the process is no longer in use. The reactions are analogous [15].

4.2.2. Processing of Bismuth-Containing Drosses

The dross resulting from the Kroll-Betterton process contains only a few percent bismuth. A typical composition is 6 % Bi, 0.8 % Ca, and 1.3 % Mg. The rest is Pb. If possible, the dross is enriched before bismuth recovery. Several methods are available: liquation, pressing with a Howard press, partial oxidation, or partial chlorination. Usually one-stage enrichment

Figure 4. The Pb–Bi–Ca–Mg system, the liquidus surface in the lead corner [15]

is insufficient, so a multistage procedure is chosen. Often tar oil is mixed with the hot dross, which then burns immediately, oxidizing part of the Mg and Ca. At the same time the lead melts and separates from the dross. The flow sheet is shown in Figure 5. The solid dross remaining can be smelted to a lead – bismuth alloy. Calcium and magnesium can be removed from the dross by adding lead chloride.

$$PbCl_2 + [Ca, Mg] \longrightarrow Pb + [Ca, Mg]Cl_2$$

The resulting Pb–Bi alloy containing 20 – 30 wt % bismuth is chlorinated at 700 – 800 °C. The lead is converted to $PbCl_2$. The crude bismuth contains less than 0.5 % lead.

A process proposed by ASARCO (Fig. 6) minimizes the costs. Vacuum filtration at 450 °C separates most of the lead without oxidation. The filter cake is heated slightly higher and burns, mostly by self-sustaining combustion. Washing with $PbCl_2$ separates the oxide residue into a Pb–Bi alloy and an oxide chloride slag. The alloy is refined in the usual way [19].

Figure 5. Conventional treatment of bismuth dross [19]

Figure 6. Bismuth treatment at ASARCO [19]

Although chlorine can be used to separate lead and bismuth, chlorine consumption is high and $PbCl_2$, not Pb, is produced. Both the Norddeutsche Affinerie, Hamburg, and the Vieille Montagne, Belgium, have chosen another method. The Bi–Cu–Mg dross is soaked in a Pb–Bi melt. The Ca and Mg are oxidized in the presence of small amounts of NaOH, < 20 kg per tonne dross. The bismuth-rich lead is cast into anodes and electrolyzed to pure lead and anode slime, which can be melted to give crude bismuth. Only the lead remaining in the crude bismuth is chlorinated. In this way the largest portion of the lead is obtained directly as metal [17], [20].

4.2.3. Electrolytic Separation of Lead and Bismuth. Bismuth Production

Some lead producers use electrolytic lead refining, usually with $PbSiF_6$–H_2SiF_6 electrolyte, which allows an almost complete lead – bismuth separation, independent of the bismuth content. Final bismuth contents $\leqq 10$ ppm can be achieved [17], [19], [21]. Almost all the bismuth goes into the anode slimes, which can contain between 2 and 25 % Bi, depending on the bismuth content of the anodes (Trail, 2 – 4 %; Oroya, 18 – 22 %; Kamioka, 22 % [2]).

At Centromin (formerly Cerro de Pasco Corp.) in La Oroya, Peru, dried anode slimes (35 % Sb, 22 % Bi, 14 % Pb, 9 % Ag, 0.03 % Au) are smelted in a reverberatory furnace to partially evaporate the antimony. The metal then is 22.9 % Sb, 30.8 % Bi, 21 % Pb, 19.6 % Ag, and 0.069 % Au. This metal is air-oxidized in a converter in two stages. In the first stage, at 900 – 1000 °C, a metal with ≈ 45 % Bi is produced. In the second stage, at 1100 – 1200 °C, a high-grade lead – silver – bismuth alloy, ≈ 50 – 55 % Ag and 30 % Bi, and a slag with 40 % Bi, 11 % Pb, 4 % Cu, and 2.5 % Sb are obtained. This slag can be reduced at 1000 – 1100 °C to crude bismuth (73 % Bi, 17 % Pb, 3.6 % Ag, 3 % Cu) [2], [22]. The flow sheet is shown in Figure 7.

The anode slimes of the electrolytic lead refinery of Consolidated Mining and Smelting Corp., Trail, Canada, contain only 2 – 4 % Bi. These anode slimes are smelted in a reverberatory furnace at 900 – 950 °C, and the resulting alloy is oxidized in two stages, at 800 – 850 °C for arsenic and antimony oxidation and at 1000 – 1100 °C for oxidation of bismuth, lead, and copper. The slag of the second stage is the raw material for bismuth recovery. It is reduced to give a Pb–Bi alloy with 25 – 30 % Bi, which is desilvered and again electrolyzed. The secondary anode slime consists mostly of bismuth. It contains 1 – 2 % Pb and only traces of other elements. The slime is reduced to crude bismuth. After treatment with chlorine to remove lead, final treatment with caustic soda yields bismuth of 99.994 % purity (20 ppm Pb, 14 ppm Cu, 33 ppm Ag). Figure 8 shows the flow sheet [2].

The lead anode slime in San Gavino Monreale is treated to produce antimonial lead and bismuth (→ Lead).

Norddeutsche Affinerie has a special status among bismuth producers. The Kroll-Betterton procedure gives a Bi–Ca–Mg dross, which is separated from lead (0.05 – 3.5 % Bi) and melted to a Pb–Bi alloy. This alloy is refined along with prerefined bismuth-rich lead in an electrolytic

Figure 7. Recovery of crude bismuth from anode slimes at La Oroya, Peru [23]

lead refinery. The anode slimes, which are rich in bismuth, are smelted directly to crude bismuth [17]. The flow sheet is shown in Figure 9. The intermediate products have the following compositions (wt %):

	Pb	Cu	Bi
Anodes	90 – 95∗	<0.01	4 – 8
Cathodes	99.99	0.0003	0.001
Anode slimes	2 – 4	0.06	88 – 90

∗ Or more.

4.3. Crude Bismuth from Copper and Tin Concentrates

Bismuth Separation from Copper Concentrates. Most of the bismuth is volatilized during smelting of the concentrates, but the flue dusts are recycled to the smelting furnaces, at least in flash smelters, so that separation at this stage is not possible. In the following converter step the bismuth (more than 50 %), along with Pb, Sb,

and As, can be separated and enriched in the flue dust, which contains several percent bismuth. After decopperization by leaching with sulfuric acid, these flue dusts are sent to lead smelters for further metal recovery. The bismuth distribution in various steps is shown in Table 6.

Figure 8. Bismuth recovery from lead anode slimes, Consolidated Mining and Smelting Co. of Canada [2]

Separate treatment of the converter flue dusts is also possible. After decopperization, bismuth can be leached out selectively with H_2SO_4–NaCl. It is precipitated as BiOCl [25].

The bismuth remaining in the blister copper is difficult to remove by distillation [26] or during copper electrolysis. The anode slimes contain considerable amounts of bismuth (Table 7), and treatment of these copper anode slimes enriches bismuth in the lead – bismuth litharge, which can be processed pyrometallurgically (see Figures 7 and 8).

Figure 9. Simplified flow sheet of lead refining and bismuth separation at Norddeutsche Affinerie, Hamburg [17]

Bismuth Separation from Tin Concentrates. Tin concentrates often contain bismuth. The bismuth can be leached with HCl and then pre-cipitated as BiOCl, a process similar to the treatment of molybdenum concentrates [6].

In Vinto, Bolivia, the 0.5 – 5 % bismuth is separated from the rich tin concentrates (55 – 63 % Sn) by volatilization during a

chloridizing roasting process in a multiple hearth furnace. Optimum volatilization occurs at 800 – 850 °C for an NaCl excess of only 25 – 50 %. A retention time of ≈ 1 h leads to a volatilization exceeding 97 %. The volatilized chlorides are absorbed in water and precipitated as BiOCl [27], [28].

If the bismuth is removed only partially or not at all from tin ores before reduction, it is reduced together with tin and can be separated with lead by vacuum distillation at ≈ 1150 °C and 10 Pa (0.1 mbar). The primary condensate is distilled again to give a secondary condensate. In this way the tin codistilled in the first distillation is recovered [29–32]. The rate-limiting step is evaporation at 1200 °C and diffusion at 1000 °C [29]. The extent of bismuth separation is shown in the following, all quantities in wt % [31], [32]:

	Sn	Pb	Bi
Crude tin	97	<2	<0.3
Primary condensate	50 – 60	10 – 40	3 – 30
Secondary condensate	2	80 – 90	<20
Refined tin	>99.97	<0.02	<0.01

5. Refining

Crude bismuth is always refined by pyrometallurgical methods, even though electrolytic refining is possible. The pyrometallurgical refining is almost identical with conventional lead refining (→ Lead), consisting of the following steps:

1) Decopperization by liquation and sulfuring
2) Te, As, and Sb removal by addition of $NaOH–NaNO_3$, the Harris process (→ Lead)
3) Removal of precious metals by Zn addition (Parkes process)
4) Lead and zinc removal by chlorination
5) Final oxidation with air in the presence of NaOH

With this procedure Norddeutsche Affinerie and Centromin produce 99.999 % Bi. The residual impurities are 2 ppm Cu, 3 ppm Zn, and 2 ppm Fe. Figure 10 shows a typical flow sheet.

Liquation slightly above the melting point of bismuth removes copper and other impurities. Copper can be removed more effectively if sulfur, soda, and charcoal are added. At 400 – 500 °C metal sulfides form, reducing the

Figure 10. Refining of bismuth at Centromin, La Oroya, Peru [23]

copper concentration to 10 ppm. The elements Se, Te, As, Sb, Sn, and Zn can be oxidized with $NaNO_3$ at 400 °C and dissolved in NaOH melt. Precious metals are removed by the addition of zinc, which forms an insoluble silver – zinc alloy (→ Lead). Just as in lead refining, removal takes place in two stages: liquation of rich and poor silver crusts. Approximately 12.5 kg Zn per tonne of Bi plus 2 kg Zn per kg of Ag are required, much greater amounts than in lead refining. The residual contents of Cu, Ni, and Co are removed during desilvering, also by for-mation of insoluble alloys. After desilvering, bismuth contains more than 1 % Zn and residual contents of lead, both of which can be reduced to a few ppm by chlorination at 400 – 500 °C. Excess chlorine can be blown out with air, or the bismuth can be washed with NaOH. Also copper, nickel, and cobalt can be removed from bismuth with chlorine [33]. The chlorination can be supported electrochemically: the bismuth melt, which is covered with a chloride melt, is the anode. Generally $NaCl–CaCl_2$ or $KCl–ZnCl_2$ melt is used. Lead and copper are converted into chlorides. Current densities can reach 0.4 – 0.8 A/cm^2 [34].

This multiple-step refining can be shortened considerably if the starting material is crust and dross from bismuth separation or anode slime from electrolytic lead refining. The quality of refinery bismuth is shown in Table 8.

Bismuth of *very high purity* is produced by vacuum distillation or zone melting. The starting material is always prerefined metal. Highest purities can be achieved by a combination of vacuum distillation and multiple zone melting. Vacuum evaporation at 800 – 850 °C and condensation at 650 – 750 °C refine bismuth almost completely. Al, Au, Ba, Be, Ca, Co, Cr, Fe, Ga, In, Ir, Li, Mo, Ni, Pd, Pt, Rh, Sn, Sr, Ti, and V stay in the residue. Cd, K, Na, Se, and Zn evaporate but do not condense. Only a few elements cannot be removed: Ag, As, Mg, Pb, and Sb are insufficiently separated. Ge, Mn, and Tl follow the bismuth. At 800 °C the distillation rate is only 3.5 kg m^{-2} h^{-1} and at 850 °C it is only 14 kg m^{-2} h^{-1}; 75 – 80 % of the feed bismuth can be evaporated [35], [36].

Multiple zone melting of distilled bismuth produces very pure bismuth. Only 1 ppm of Ca, Pb, and Si and a total of 1.5 ppm of Al, Ca, Fe, and Mg are found.

Smelting bismuth with NaOH at 400 °C completely removes As, Sb, Sn, and Zn and almost completely slags Te and Pb. Careful chlorination before distillation and zone melting is recommended [37]. Treatment with chlorine removes Cu, Pb, Sn, and Zn completely. Zone melting then enriches Ag, Cu, Ni, Pb, Se, Sn, Tl, and Zn in the end piece of the rod.

6. Bismuth Alloys

The binary systems of alkali metals or alkaline-earth metals with bismuth show intermetallic compounds with high melting points. In the system Bi–Li, for example, the compound Li_3Bi melts at 1145 °C. Some intermetallic compounds, especially those with K, Ca, and Mg, are or were used to separate bismuth from lead (see Section 4.2.1). The systems with Zn, Al, Ga, Co, or Si show limited solubility in the liquid phase. Bismuth and iron are insoluble in one another; therefore, iron equipment can be used for melting and refining the metal. The rare case of complete solubility in both the liquid phase and the solid phase appears in the system Bi–Sb. Some binary alloys, particularly those with Cd, In, Pb, Sn, and Tl, as well as some multicomponent alloys, form low-melting eutectics (Table 9). The most common ones, called fusible alloys, are offered under the trade names Asarcolo, Cerrolow, Cerrobend, Belmont, and Ostalloy.

Some multicomponent and some non-eutectic compositions have both low melting points and the unusual characteristic of not contracting or even expanding on solidification. The alloy with 56 % Bi, 20 % Sn, and 24 % Pb is said to have the largest volume expansion of any alloy [6]. Some alloys show effectively no volume change: 50 % Bi – 50 % Pb and 70 % Bi – 30 % Pb, for example.

Bismuth forms with alkali metals and alkaline-earth metals alloys that superconduct at low temperatures. Examples are LiBi, NaBi, $CsBi_2$, and $BaBi_3$. Their transition temperatures are 2.47 K, 2.22 K, 4.75 K, and 4.69 K, respectively.

Bismuth alloys are usually prepared by melting the components together, but prealloyed metals are used for the exact adjustment of the composition.

Bismuth is used as an alloy addition in steel and aluminum. The fabrication of low-carbon steel and stainless steel is improved by addition of 0.15 % Bi and 2.2 % Pb. To aluminum alloys 0.2 – 0.7 % each of bismuth and lead are added [6].

Uses. The versatility of bismuth alloys results from their extremely low melting points and their volume changes on solidification combined with low viscosity and low surface tension. The composition can be chosen so that the alloy contracts, remains the same, or expands as a result of solidification. The last two cases, because they are unusual, are the most important.

The eutectic alloy Bi–Cd–In–Pb–Sn, melting at 47 °C, and some alloys melting higher are used for the automatic release of fire alarm systems, automatic sprinkler systems, electric fuses, and safety plugs for storage tanks.

Thin-walled tubes and parts for the automobile and aviation industries are covered or filled up with bismuth alloy melting below 100 °C before bending or deforming to prevent collapse. After forming, the alloy can be melted out by dipping the part into boiling water. Especially suitable is the eutectic alloy Bi – Cd – Pb – Sn, which melts at 70 °C. It is very ductile and expands on solidification and during the first hour thereafter; therefore, it keeps the worked part under tension during bending or forming.

Table 8. Composition of refinery bismuth [4]

	Bi, wt %	Contents, ppm				
		Cu	Ag	Zn	Pb	Fe
Centromin, La Oroya	99.999	2	–	3	–	2
Norddeutsche Affinerie, Hamburg	99.999	–	–	–	–	–
Cominco, Trail, Canada	99.999	–	–	–	–	–
Mitsui, Kamioka	99.99	6	9	–	10	–
San Gavino, Sardinìa	99.99	10	15	–	10	–

The noneutectic alloy with 48 % Bi, 28.5 % Pb, 9 % Sb, and 14.5 % Sn, which melts over the range 103 – 227 °C, expands greatly during the first hours after casting, reaching its final volume after ≈ 500 h. It can be used to grip tubes, tools, punches, and parts to be machined. Because it is diamagnetic, it is suited for embedding magnets in equipment or filling the space between magnets.

The noneutectic Bi–Sn alloy with 40 % Bi and 60 % Sn, which melts over the range 138 – 169 °C, contracts only 0.01 % during solidification and aging. Such an alloy exactly reproduces the shape and dimensions of the casting mold. In sprayed parts it reproduces the base in every detail. This alloy is used for test casts, copies of irregular parts, molds for thermoplastic material in the rubber and plastic industry, and for meltable casting cores. The eutectic Bi–Sn alloy with 57 % Bi, melting at 138 °C, expands 0.07 % on solidification but contracts during the next 5 h. The final net expansion is only 0.02 %. This alloy is used in dentistry for the production of models and molds [39].

Some bismuth alloys wet glass, mica, and enamelled ceramics. They are used to seal such substances to each other and to metals, as well as to produce high-vacuum seals for glass equipment. A so-called bismuth cement consists of 35 % Bi, 37 % Pb, and 25 % Sn. Such alloys are used in holding devices for grinding and polishing glass and plastic lenses. Low-melting bismuth solders are used for the soldering of temperature-sensitive electronic parts [40].

Cs–Bi alloys are used in photocathodes (→ Photoelectricity). The low conductivity of bismuth results in a good quantum yield. Bismuth tellurides and a bismuth – antimony alloy with 11 % Sb are used in photoelectric infrared detectors. The compound Bi_2Te_3, especially its solid solutions with Bi_2Se_3 and Sb_2Te_3, is a use-ful thermoelectric material (→ Thermoelectricity). The system $AgSbTe_2$ – $AgBiTe_2$ also has interesting thermoelectric properties [41]. Mn – Bi alloys are permanent magnets [34].

Table 9. Fusible alloys [6], [38]

System	Eutectic composition, wt %	Eutectic temperature, °C
Cd – Bi	Cd 40, Bi 60	144
In – Bi	In 66.3, Bi 33.7	72
	In 33, Bi 67	109
Pb – Bi	Pb 43.5, Bi 56.5	125
Sn – Bi	Sn 43, Bi 57	139
Tl – Bi	Tl 23.5, Bi 76.5	198
	Tl 52.5, Bi 47.5	188
Pb – Cd – Bi	Pb 40, Cd 8, Bi 52	92
Sn – Cd – Bi	Sn 26, Cd 20, Bi 54	102
In – Sn – Bi	In 16, Sn 26, Bi 58	79
Tl – Pb – Bi	Tl 11.5, Pb 33.3, Bi 55.2	91
	Tl 48, Pb 9.8, Bi 42.2	186
Tl – Sn – Bi	Tl 14.3, Sn 35.7, Bi 50	124
	Tl 25, Sn 31, Bi 44	167
Pb – Sn – Cd – Bi	Pb 26.7, Sn 13.3, Cd 10, Bi 50	70
In – Cd – Pb – Sn – Bi	In 19.1, Cd 5.3, Pb 22.6, Sn 8.3, Bi 44.7	47
	In 4.0, Cd 9.6, Pb 25.6, Sn 12.8, Bi 48.0	64

In nuclear technology, bismuth and its alloys may be useful for cooling and as heat-exchange mediums because bismuth has an extremely low absorption cross section for thermal neutrons. However, nothing specific has been reported about use in modern reactors.

Table 10. Physical properties of inorganic bismuth compounds

Compound	Formula	M_r	Gibbs free energy of formation, kJ/mol	Density, g/cm^3	*mp*, °C	*bp*, °C
Bismuth tribromide [*7787-58-8*]	$BiBr_3$	448.71	− 263.8	5.72	219	461

7. Bismuth Compounds

7.1. Inorganic Compounds

In its inorganic compounds bismuth usually has + 3 or + 5 oxidation state. The + 5 oxidation state is a strong oxidation agent, e.g., $NaBiO_6$ or BiF_5. Bismuth has an oxidation state of − 3 in a few intermetallic compounds, e.g., Li_3Bi and $CaMg_2Bi_2$. In gases, such as BiCl or BiO, in $Bi(AlCl_4)$, and in alloy-like compounds, such as BiS or BiSe, bismuth can have + 1 or + 2 oxidation state, and + 1, 0, and − 1 are present in polynuclear ionic species. However, the + 1 and + 2 states are rare, and compounds with + 4 probably do exist also. On dissolution, bismuth compounds hydrolyze easily, yielding nearly insoluble basic salts of the type BiOX. In the presence of strong acids or in complexing agents, bismuth remains in solution. Table 10 shows some physical properties of the most important inorganic bismuth compounds.

Only a few inorganic bismuth compounds are produced commercially. Bismuth oxychloride is used in cosmetics. It is the basic ingredient of a pearly pigment found in eye shadow, hair sprays, powders, nail polishes, and other cosmetic products (→ Pigments, Inorganic). Bismuth oxide can substitute for lead oxide in glass or porcelain.

The use of bismuth compounds in *medicine* is decreasing and the use of bismuth in pharmaceutical products is being viewed more and more as a questionable practice [42]. France, which in 1972 consumed more than 1000 t of bismuth, making it the largest bismuth consumer, has restricted the use of bismuth in pharmaceuticals, resulting in a sharp drop in bismuth consumption [43]. Bismuth compounds have been used because of their astringent, antiphlogistic, bacteriostatic, and disinfecting actions. In dermatology bismuth subgallate is still used in vulnerary salves and powders as well as in antimycotics. Medicines for depigmentation can no longer contain bismuth. Even bismuth subcarbonate, bismuth subnitrate, or complex bismuth citrates ought not be used for the treatment of gastric disturbances.

Bismuth Tribromide, $BiBr_3$. Golden-yellow crystals, cubic, hygroscopic. Prepared by reaction of the elements at 250 °C [44] or in methanol [45], by reaction of bismuth with molten iodine bromide and extraction with CCl_4 [46], or by dissolving Bi_2O_3 in concentrated hydrobromic acid, drying, and distillation in a stream of nitrogen. Bismuth tribromide is soluble in acetone, ether, acetic acetate, glacial acetic acid, and aqueous solutions of HCl, KCl, KBr, and KI. In water it hydrolyzes to BiOBr. It is insoluble in alcohol and carbon disulfide.

Bismuthyl Carbonate, $(BiO)_2CO_3$. Naturally occurring as bismutite. White powder, sensitive to light, decomposition during heating. Preparation by precipitation with sodium or ammonium carbonate from nitrate solutions [47], [48].

Bismuth Trichloride, $BiCl_3$. White powder, cubic, very hygroscopic. Prepared by chlorination of the molten metal [44] or by dissolution of

the metal in aqua regia, boiling down, and distillation. *Bismuth chloride oxide,* bismuth oxychloride, BiOCl, is formed by heating $BiCl_3$ in air or by hydrolysis of $BiCl_3$. The oxychloride is a white, lustrous, crystalline powder, ϱ 7.72 g/cm^3, that is practically insoluble in water, ethanol, acids, and bases. Hot concentrated alkali solutions convert it into the trioxide.

Bismuthine, BiH_3. Bismuthine [*18288-22-7*] is a colorless gas unstable at room temperature. Prepared by treating Mg_3Bi_2 with dilute acids [49], decomposition of methylbismuthine or dimethylbismuthine [50], or reaction of bismuth halides with $LiAlH_4$ in a vacuum [3].

Bismuth Trifluoride, BiF_3. White, fine pow-der, rhombic. Prepared by dissolving Bi_2O_3 in hydrofluoric acid [51] or by precipitation from an aqueous solution of bismuth trinitrate with aqueous KF or NaF [52]. Soluble only in acetone and liquid organic acids, insoluble in water. *Bismuth fluoride oxides* [*13520-72-4*], BiO_xF_{3-2x}, form when $BiF_3$is heated in air at 670 – 850 °C.

Bismuth Pentafluoride, BiF_5. White needles, formed by fluorination of bismuth metal or BiF_3 at 500 °C [53]; strong oxidant, violent reaction with water.

Bismuth Triiodide, BiI_3. Greenish-black crystalline powder. Prepared by heating stoichiometric quantities of the elements in a sealed vessel at 150 – 180 °C [54] or by reaction of concentrated hydriodic acid with a solution of $BiCl_3$ in hydrochloric acid [55]. Insoluble in cold water. Boiling BiI_3 with water produces BiOI. Bismuth triiodide is soluble in alcohol, natural gasoline, xylene, and toluene. Red triammine complexes are formed in aqueous ammonia. The yellowish-orange Dragendorff reagent, $KBiI_4$, for precipitating alkaloids, is formed by dissolving BiI_3 in potassium iodide solution.

Bismuth Trinitrate Pentahydrate, $Bi(NO_3)_3 \cdot 5\,H_2O$. Colorless, columnal crystals. Prepared by dissolving bismuth metal, Bi_2O_3, or $(BiO)_2CO_3$ in nitric acid [56]. Hydrolyzes in water to basic salts. The nitrate is soluble in strong inorganic acids, glacial acetic acid, and glycerol. It is the starting material for basic bismuth nitrates of composition $x\,Bi_2O_3 \cdot y\,N_2O_5 \cdot z\,H_2O$. Bismutum subnitricum, approximate composition $6\,Bi_2O_3 \cdot 5\,N_2O_5 \cdot 9\,H_2O$, was commonly used for medical purposes.

Bismuth Oxides. Bismuth trioxide, Bi_2O_3, is the only bismuth oxide which has been isolated in a pure state. There is also a Bi_2O_5, but its characteristics are not yet well defined. Information about other oxides and related compounds is scarce.

Bismuth trioxide, Bi_2O_3, is prepared by oxidation of bismuth metal at 750 – 800 °C, by thermal decomposition of carbonates, or by addition of alkali-metal hydroxides to a bismuth salt solution. In the last case hydrated bismuth trioxide precipitates. This gelatinous compound is usually represented by the formula $Bi(OH)_3$; calcining it yields Bi_2O_3.

Monoclinic α-Bi_2O_3 converts in an endothermic transition at 710 – 740 °C to the high-temperature cubic modification δ-Bi_2O_3, which is stable between 710 °C and the melting point. The transition is reversible, and δ-Bi_2O_3 is not stable at room temperature. Quenching thin layers of molten Bi_2O_3 forms metastable tetragonal β-Bi_2O_3, which converts back to α-Bi_2O_3 when heated. This metastable β-Bi_2O_3 dissolves oxygen in its lattice without a structure change; the composition can range from $BiO_{1.50}$ to $BiO_{1.75}$. Heating β-$BiO_{>1.50}$ to 750 °C and quenching at a moderate rate forms metastable cubic γ-Bi_2O_3, which contains more oxygen than the stoichiometric formula Bi_2O_3 expresses. The preparation of all these modifications is described in detail in [3].

Quenching molten mixtures of Bi_2O_3 and other metal oxides from 800 – 1000 °C to 0 °C produces stabilized δ- and β-modifications; tempering for 24 h at 600 °C yields a γ-modification contaminated with other oxides.

Bismuth trioxide is soluble in strong inorganic acids and concentrated alkaline solutions containing glycerol. Above 710 °C it attacks metal oxides; in fact, molten bismuth trioxide dissolves every metal oxide and even corrodes platinum.

Bismuth trioxide monohydrate [*1304-76-3*], $Bi_2O_3 \cdot H_2O$, is a white powder. Its composition and constitution are not completely elucidated.

$Bi(OH)_3$ and BiOOH probably do exist. A hydrated oxide precipitate is formed by reaction of an acidic bismuth nitrate solution with ammonia or caustic soda solution [57].

Bismuth pentaoxide [*35984-07-7*], Bi_2O_5, is prepared by oxidizing suspended Bi_2O_3 with Cl_2, Br_2, or H_2O_2 in an aqueous alkaline solution. Each of these reactions goes almost to completion. Molten mixtures of Bi_2O_3 and alkali-metal oxides can be oxidized by air or oxygen. The reaction is favored by excess alkali. The excess alkali can be stripped with methanol at 0 °C to form yellowish-orange sodium metabismuthate, $NaBiO_3$. Addition of nitric or perchloric acid leads to a compound whose composition varies from $Bi_2O_4 \cdot x\,H_2O$ to $Bi_2O_5 \cdot x\,H_2O$. Both compounds are strong oxidants.

Bismuth Trisulfide, Bi_2S_3. Naturally occurring as bismuth glance. Dark brown to grayish black, metallic luster, rhombic. Prepared by heating bismuth with sulfur or bismuth trioxide with sulfur compounds or by precipitation from aqueous bismuth(III) solutions with H_2S. It is insoluble in water and alkaline solutions but soluble in hot aqueous salt solution or concentrated nitric acid. Concentrated alkaline metal sulfide solutions or melts dissolve Bi_2S_3 to form compounds of the type $KBiS_2$. Similar compounds naturally occur with copper, silver, and lead.

7.2. Organic Compounds

There are numerous stable organobismuth compounds [3], [58–64]. The bismuth is either trivalent or pentavalent. The compounds are more subject to thermal decomposition than the corresponding phosphorus, arsenic, and antimony compounds, and they are more toxic. Both statements are especially true for halogeno- or pseudohalogenoorganobismuth compounds.

Trivalent Organobismuth Compounds (Bismuthines). Symmetrical tertiary bismuthines, R_3Bi where R is alkyl or aryl, are best prepared by reaction of organometallic reagents, usually Grignard compounds, with anhydrous $BiCl_3$ or $BiBr_3$ in a dry inert atmosphere. Although triarylbismuthines are stable, all trialkylbismuthines except trimethylbismuthine [*593-91-9*] are self-igniting in air. Tertiarybismuthines react exothermically with halogens, and they decompose in thepresence of water or alkaline solutions. Inorganic bismuth salts are formed in the presence of strong mineral acids.

Halo- and pseudohaloorganobismuthines are sensitive to oxygen and moisture and tend to self-ignition. They are produced by reaction of tertiary bismuthines with $BiCl_3$. Generally they are crystalline solids melting between 180 and 205 °C.

Pentavalent Organobismuth Compounds. After the tertiary bismuthines, the triarylbismuth dihalides are the most important organobismuth compounds. Only the chlorides and bromides can be prepared in high yields by oxidation of triarylbismuthines with the stoichiometric amount of chlorine or bromine. To prevent decomposition this has to be done at 0°C. Other triarylbismuth dihalides cannot be produced this way because of instant decomposition. Instead they are produced by reaction of triarylbismuth dichlorides or dibromides with alkali-metal or silver halides.

8. Chemical Analysis

For qualitative determination bismuth [65] is precipitated as Bi_2S_3 from slightly acidic solution with H_2S. The precipitate is brown black and soluble in strong acids and hot dilute nitric acid. Yellow-green Bi_2S_3 precipitates from alkaline solution on addition of Na_2S. Bismuth can be precipitated by hydrolysis from hot dilute hydrochloric acid as bismuth oxychloride, provided excess chloride ions are absent. Aqueous ammonia precipitates bismuth as white bismuth oxide hydrate, which can be reduced to bismuth metal with alkaline stannate(II) solution.

Bismuth phosphate, $BiPO_4$, can be precipitated quantitatively from very dilute nitric acid solution. Bismuth in medicinal preparations is determined by precipitation as basic bismuth carbonate. Calcining at 550 °C yields Bi_2O_3. A thiourea – bismuth mixture is of yellow color in nitric acid solution, and this is the basis for a photometric method. If ions such as Fe, Hg, Zr, etc., are absent, titration with EDTA is a selective, quantitative, and fast method of bismuth

analysis. This method has become very popular [66]. Emission, mass, or atomic absorption spectrometry allow detection of less than 1 ppm Bi.

9. Economic Aspects

Bismuth concentrates are a byproduct of nonferrous metal ore dressing. The metal available from concentrates has remained nearly the same, between 3600 and 4600 t/a since the 1960s. The world's one and only bismuth mine, Telamayu in Bolivia, which had produced about 15 % of the worldwide supply, stopped production in 1980 because of either declining demand or perhaps total exhaustion of the site. Also Australia and Peru are reducing their production. Only a part of bismuth refining is carried out in the mining countries. Table 11 shows the metal content of bismuth ores and concentrates, corresponding closely to the world production of 3795 t in 1980. The main producer of bismuth metal is the United States, producing $\approx$ 950 t/a [68]. Bismuth suppliers are listed in [70].

Bismuth (99.99 %) is quoted in London and New York in \$/lb (1 lb = 0.454 kg). After rising to 9 \$/lb in 1974 the price of bismuth fell steadily for years. The price was \$ 1.67 per pound in December, 1983. However, since then the price has increased, to \$ 6.60 in February, 1985. The prices are much higher for high-purity bismuth (99.999 %). Table 12 shows actual U. S. bismuth consumption. No consumption data for the European market have been published for several years. Because of substitution and regulatory restrictions bismuth consumption has decreased more in Europe than in the United States.

10. Toxicology and Occupational Health

Toxicology. Poisoning by bismuth [*7440-69-9*] and bismuth compounds has occurred more frequently during medical therapy using soluble compounds than by exposure at the workplace [71], [72].

Bismuth poisoning resembles in part poisoning caused by lead and mercury and their compounds. After oral administration, water-insoluble bismuth compounds such as bismuth nitrate oxide and bismuthyl nitrate [*1304-85-4*], $BiO(NO_3)$, are hardly absorbed, and acute poisoning is seldom. Increased absorption was observed, however, when large quantities of such compounds were applied to skin lesions, resulting in serious poisoning, sometimes fatal. Water-soluble bismuth compounds are absorbed quickly, and acute poisoning is likely to occur. A significant biochemical effect of bismuth incorporation is the increase in metallothionein concentration that occurs in rats after subcutaneous administration of bismuth chloride [*7787-60-2*] atdoses of 1 x 3 mg or 7 x 3 mg Bi/kg body weight, influencing the renal andhepatic levels of Cu and Zn [73]. There are indications that pretreatment with bismuth compounds protects mice and rats against the toxic effects of anticancer drugs [74].

The main hazard of bismuth is the chronic exposure that took place during long-term therapy of gastric ulcera (up to 30 years in some cases) practiced earlier in Australia and France. Such exposure can have serious consequences; even deaths can occur [75]. However, the relatively high toxicity of bismuth nitrate oxide and bismuth subnitrate [*1304-85-4*], which was observed especially in children, is most likely not caused by bismuth but by reduction of nitrate to nitrite by intestinal bacteria and subsequent methemoglobin formation [71], [72].

Initial symptoms of chronic intoxication by large amounts of bismuth compounds are hypersalivation, stomatitis, and a grayish blue seam surrounding the gums (symptoms similar to those caused by lead). According to many investigations [75–77], long-term oral administration caused encephalopathies accompanied by confusion, distractions, ataxia, myoclonic spasms, dysarthria, insomnia, damage to the kidneys (albuminuria, nephritis) and headache in many cases, and less frequently epileptic attacks. Some cases ended in death, the brains of the deceased containing large quantities of lipid-soluble bismuth compounds [78]. Symptoms were mostly reversible within several weeks or months after cessation of bismuth intake. The crossing of the blood – brain barrier by bismuth compounds was also demonstrated in other experiments, e.g., for trivinylbismuth in pigs [79]. In another epidemiological study, a group of patients with manifest bismuth poisoning was compared to a control group that had been exposed to the same amount of bismuth but that

did not show any symptoms of poisoning [80]. The investigators concluded that bismuth poisoning is caused by the transformation of low-toxicity bismuth compounds into highly toxic compounds by intestinal bacteria. Bismuth toxicity is enhanced significantly when applied intraperitoneally as a Bi – L-cysteine complex to mice [81].

Apparently, symptoms of neurotoxicity caused by bismuth compounds such as tripotassium dicitrato bismuthate (de-nol) [*57644-54-9*] [82], colloidal bismuth subcitrate [*57644-54-9*], and bismuth subnitrate [83] were causedby an excessive intake, since the normal clinical use of these two compounds in the treatment of gastric ulcera did not cause signs of neurotoxicity, as shown by clinical and neurophysiological tests that included magnetic resonance imaging, nerve-conduction studies, visual evoked responses, electroneurography, and electroencephalography. However, decreased kidney function may increase the risk of bismuth intoxication, even by therapeutic doses of bismuth compounds [84].

The occurrence of osteolytic and osteonecrotic arthropathies of the shoulder was pointed out in [85]. In over 59 cases of bismuth poisoning, bone lesions accompanied by encephalopathies were described [86]. As a result of the elimination of bismuth compounds in the urine, albuminuria and nephritis were also observed [72]. Bismuth also causes eye defects [87], which was confirmed by experiments with mice [88]. Inhalation of trimethylbismuth [*593-91-9*] by humans causes irritation of the respiratory tract and conjunctiva. Cats and dogs that inhaled trimethylbismuth for 10 – 20 min showed ataxia, restlessness, and convulsions; after 24 h severe encephalitis was observed [89]. Furthermore, the skin shows pigmentation, purulent pustules, and severe dermatitis.

For the treatment of bismuth poisoning, a series of heavy-metal chelators that enhance the excretion of bismuth is avail-

able. On the basis of experiments on rats, the chelators of choice for clinical practice are *meso*-2,3-dimercaptosuccinic acid (DMSA) and D,L-2,3-dimercaptopropane-1-sulfonic acid (DMPS) [90]. However, only in a small number of cases is the application of chelators such as DMPS or D-penicillamine actually necessary [72].

In a long-term carcinogenicity test, bismuth chloride oxide [*7787-59-9*], BiOCl, was fed to rats over a period of two years (1, 2, and 5 % in the feed) [91], and neither carcinogenic nor other toxic effects that were attributable to bismuth chloride oxide could be found. With the exception of rare single reports, there are no indications so far for carcinogenicity, mutagenicity, immunotoxicity, or reproductive toxicity, including teratogenicity, of bismuth compounds: Bismuth trioxide caused chromosomal aberrations in mice after the intake of 400 – 1000 mg/kg body weight [92]. The following toxicological data (in mg/kg) are available for bismuth and bismuth compounds: bismuth, LDLo (human, presumably oral): 221 [93]; bismuth chloride oxide, LD_{50} (rat, oral): 22 000; trimethylbismuth, LD_{50} (rabbit, oral): 484, LD_{50} (rabbit, s.c.): 182, LDLo (rabbit, i.v.): 11 [89].

Occupational Health. Bismuth and its compounds are not included the list of German MAK values or in the lists of carcinogenic or sensitizing workplace compounds [94]. Occupational safety and health guidelines for (undoped) bismuth telluride [*1304-82-1*], Bi_2Te_3:OSHA PEL: 15 mg/m^3(total dust) and 5 mg/m^3(respirable fraction) as an 8-h TWA [95]; NIOSH Recommended Exposure Limit (REL): 10 mg/m^3(total dust) and 5 mg/m^3(respirable fraction) as an 8-h TWA [96]; ACGIH TLV: 10 mg/m^{3}as a TWA for a normal 8-h working day and a 40-h working week [97].

4.1.2. Mechanical Pulp
4.1.3. Paper Recycling (Deinking)
4.1.4. Environmental Aspects of Pulp Bleaching
4.2. Textile Fibers
4.3. Other Products

Bleaching is the removal of color from various materials. It is predominantly achieved by an oxidative or reductive treatment, which destroys chromophores. In principle all oxidizing or reducing chemicals can act as bleaching agents, but on an industrial scale only a few compounds are used in bleaching processes. Chlorine dioxide, hydrogen peroxide, and sodium dithionite are predominantly applied. The alternative to a chemical reaction is the adsorption of colored impurities on pigment surfaces, like active carbon or bleaching clays. This method is applied mainly in purification or bleaching of liquids.

A bleaching process removes impurities; thus, in parallel the bleached good is cleaned. The “art of bleaching” is to reach a desired decrease in color with the least negative impact on quality and properties of the bleached material. Chemicals and processes are selected on the basis of their ability to achieve brightness and quality targets with a small amount of byproducts or residuals and low impact on the environment.

Bleaching of fibers for paper production is the most important industrial application. Highest effectiveness is guaranteed by a combination of several process steps in a bleach plant. Textile fabric bleaching is the second most important application. Modern bleaching technology aims for the most moderate use of resources, the lowest consumption of water, and best biodegradability of the compounds dissolved during the bleaching process.

[Top of Page]

1. Introduction

A bleaching effect is achieved by a removal of chromophores. This can be achieved by adsorption of the colored compounds on active surfaces like active carbon or bleaching clays. On an industrial scale this option is used to bleach and purify liquids like vegetable oil. Bleaching by chemical destruction of chromophores in organic or inorganic compounds is more common. Industrially, decolorization is often combined with purification or cleaning. Components affecting material quality, handling properties, or marketability of a product are removed. This is especially important for natural products, most of which contain impurities. For example, cotton is contaminated with seed-capsule residues, wax, fatty constituents, and inorganic compounds. Bleaching cotton increases brightness while simultaneously removing impurities. Bleaching also can continue or supplement an earlier processing step. For example, in continuation of chemical pulping bleaching removes lignin from wood fibers, thus brightening and further purifying the cellulose.

Very few compounds can be bleached nearly colorless without damage. The “art of bleaching” is to achieve a high degree of chromophore removal without damaging the bleached good. The aim of bleaching from the outset may also be to generate simply a more uniform hue, e.g., bleaching wood veneer.

In terms of the amount of material processed and the value of the product, bleaching of fibrous materials for paper and textile production is most important (Table 1). Detailed information about these processes is available under specific keywords (⟶ Paper and Pulp or ⟶ Textile Dyeing) and in [1], [2], [3]. Table 2 gives a summary of products bleached on industrial scale.

Table 1. World production of bleached fiber material (10^3 t)

Material	Year	Amount
Bleached chemical pulp	2004	80 000
Bleached mechanical pulp	2004	30 000
Cotton*	2004/2005	25 000
Wool (scoured)*	2003	1 260

*Dying is an important part of textiles manufacturing. A prerequisite of the dying process is a certain level of cleaning and bleaching in order to achieve uniform color distribution. It can be assumed that the predominant amount of fiber used for textiles production has been bleached during manufacturing.

Table 2. Important products requiring bleaching

Fibers for paper	
Chemical pulp,	
Mechanical pulp,	
Wastepaper, linters	
Fibers for textiles	
Natural products:	cotton, flax, wool, silk
Synthetics:	rayon, polyamide, polyester, polyacrylonitrile, polyurethane
Others	
Vegetable products:	fatty acids, resins, wax, starch, flour, vegetable oils, wood, wood veneer, peeled rattan
Animal products:	fatty acids, hair, bristle, feathers, horn, sponges, mother-of-pearl
Mineral and synthetic products:	paraffin, petroleum, glues, plastics, soap, sulfuric acid

Bleaching can be classified into oxidative and reductive bleaching. Oxidative bleaching destroys chromophores irreversibly, while reductive bleaching can be reversible, for example, by reoxidation by atmospheric oxygen.

Especially in the case of natural products, the chemical constitution of the colored compounds is not known in full detail. Generally these compounds contain conjugated carbon – carbon double bonds, e.g., polymethine chains, aromatic systems, or quinoid systems. Oxidative bleaching destroys the double bonds, removes the conjugation, and produces chemical compounds of lower molecular mass. Effective bleaching frequently is a multistep process. The repetition of acidic oxidation

and alkaline extraction allows moderate conditions and a low concentration of chemicals to be maintained.

The bleaching effect is measured by the increase in brightness. Remission photometers are used to determine brightness relative to a standard at several wavelengths. $BaSO_4$ is the most widely used standard. However, there are several similar methods that may be used to determine brightness [4], [5]. The quality and efficiency of bleaching is also reflected by brightness stability. Excessive oxidation can generate new chromophores or the potential for later yellowing. Yellowing takes place if the auxochrome groups in a chromophore can be reoxidized. Light and heat may change the color of bleached materials. Carbon – carbon bonds are readily cleaved by UV radiation to give radicals. Recombination of these radicals with oxygen or other parts of the molecule can form new chromophores.

In a bleaching processes the degree of polymerization of the polymers treated must not be affected negatively. A decrease in molecular mass of the polymers may affect fiber strength and reduce the economic value. Therefore, bleaching should destroy chromophores but not affect the molecular structure. A wide variety of bleaching methods have evolved because of the various complications resulting from the differences in the raw materials. An example is bleaching of cotton in comparison to wool. While strong alkaline conditions can be applied in bleaching the carbohydrate polymer cellulose (cotton), the keratin (protein) wool fiber is very sensitive towards alkali. Extraction of amino acids would destroy the polymer, so alkaline bleaching cannot be used.

[Top of Page]

2. Bleaching Agents

Detailed descriptions of the production and properties of bleaching chemicals are given under the specific keywords (for example, ⟶ Chlorine). The following sections are limited to a description of the applications and the advantages or disadvantages of the major bleaching agents.

2.1. Pretreatment

The removal of contaminants is part of the preparation for a bleaching process. A typical pretreatment might simply be washing. Sheared wool can contain up to 50 wt % of sand and fatty material (lanolin). Similarly, compounds consuming or decomposing the bleaching agent must be eliminated before the actual bleaching process. Washing ahead of bleaching in the presence of surfactants or chelating compounds is a common procedure. This decreases the demand for bleaching agent and lowers the potential for negative side reactions during bleaching. In chemical pulp bleaching this can be an important prerequisite of bleaching.

Acid washing below pH 3 solubilizes metal ions. The presence of reducing agents such as sulfur dioxide to lower the oxidation state of the metals can improve the effect. Chelating agents like the sodium salts of diethylenetriaminepentaacetic acid [140-01-2], DTPA, or ethylenediaminetetraacetic acid [64-02-8], EDTA, are used under mildly acidic conditions (pH 5–6) to accelerate the elimination of metals. This pH range allows the removal of transition metals with conservation of magnesium and calcium ions, which are of benefit as stabilizers in bleaching. For chemical pulp produced by alkaline pulping, such a metals-removal stage is necessary if totally chlorine free (TCF) bleaching is to be applied. In conventional or ECF (elemental chlorine free) bleaching metals are removed during the acidic chlorine dioxide stages. In acid sulfite pulping they are solubilized during the pulping process and removed in brown stock washing.

During alkaline pulping of hardwood xylan polymer double bonds are generated. These hexenuronic acids consume electrophilic bleaching chemicals. They are hydrolyzed in a hot acid pretreatment below pH 3 at about 90 °C to yield furancarboxylic acid [6]. This decreases the demand for bleaching chemicals.

Enzymes like xylanase may be applied as pretreatment. During alkaline pulping xylan dissolves but may precipitate again in the final steps of the cooking procedure. This can cause difficulties in bleaching. Xylanase removes the precipitate and facilitates bleaching. Preferred products are enzymes extracted from thermophilic bacteria with high temperature and pH tolerance.

In bleaching of textiles, treatment with amylase or peroxosulfate may be necessary to remove starch.

2.2. Oxidizing Agents

The ancient Egyptians and Phoenicians practiced oxidative bleaching of textiles in sunlight combined with a mild alkaline treatment using potassium carbonate leached from wood ashes. In the 1700s bleaching of textile fabrics by an alternating treatment with potassium carbonate, sunlight on grassy meadows, and sour milk was known as “Dutch bleaching”, because it reached its greatest perfection around Haarlem, in the Netherlands.

The increase in knowledge about chemistry in the late 1700s yielded a new bleaching agent, hypochlorite. For nearly 150 years the hypochlorites of potassium [7778-66-7] (Eau de Javelle), sodium [7681-52-9] (Eau de Labarraque), and calcium [7778-54-3] developed into the most important industrial bleaching agents. Chlorine was introduced in chemical pulp bleaching in the 1930s. Chlorine dioxide and hydrogen peroxide followed a decade later.

Industrial use of oxygen as a bleaching agent for chemical pulp started in the late 1960s. Ozone [10028-15-6] was later added to chemical pulp bleaching sequences. Other oxidizing compounds used for bleaching are derivatives of hydrogen peroxide, for example, peracetic acid, sodium perborate, peroxodisulfates (persulfates), and peroxomonosulfates (Caro's acid). These compounds are applied only under special conditions. This also applies for potassium permanganate [7722-64-7].

2.2.1. *Oxygen (⟶ Oxygen)*

The use of oxygen [7782-44-7] as a bleaching agent has increased sharply since the early 1970s. It is used in chemical pulp

bleaching to continue and intensify the lignin degradation process which normally starts with alkaline pulping. Oxygen delignification needs alkaline conditions (normally NaOH) for the oxidation process, a rather high temperature (75 – 100 °C), and an oxygen pressure of 0.3 – 0.5 MPa. Increasing the temperature, the pressure, or the caustic soda concentration increases the rate of oxidation. Oxygen delignification involves two simultaneous reactions: the desired delignification and undesired carbohydrate degradation. Therefore practical limits exist for temperature increase and the amount of alkali. The decrease in the degree of polymerization is inhibited to some extent by magnesium salts.

Although the effect of oxygen on chemical pulp is limited, treatment with oxygen decreases the demand for other bleaching chemicals by 40 – 50 %. Oxygen delignification allows the combined recovery of the effluents from pulping and the subsequent delignification step, effectively lowering the total amount of organic material discharged from the bleaching plant.

For magnesium-based pulping processes (magnesium sulfite pulping), the oxygen stage can be operated with magnesium hydroxide or oxide as the alkali source. Typically, hydrogen peroxide is added simultaneously (at about 90 °C) to increase the rate of delignification.

2.2.2. *Chlorine Dioxide and Sodium Chlorite (* ⟶ Chlorine Oxides and Chlorine Oxygen Acids*)*

Chlorine dioxide [10049-04-4] is a very selective bleaching agent. The first industrial use in bleaching chemical pulp was in 1946.

Chlorine dioxide has an unpaired electron; therefore, it is a free radical and has limited stability. It is a gas under standard conditions and explodes spontaneously at partial pressures above 40 kPa, decomposing into chlorine and oxygen. If heated or exposed to light, it can explode even at lower concentrations, but with less violence. For this reason, pure chlorine dioxide cannot be transported and stored. It is generated on site and normally handled as dilute aqueous solution.

The basic reaction for industrial chlorine dioxide generation is the reduction of chlorate [14866-68-3]. Historically, reduction with sulfur dioxide, the Mathieson process, is important:

$$2\,NaClO_3 + SO_2 \xrightarrow{H_2SO_4} 2\,ClO_2 + Na_2SO_4$$

Dilute sulfuric acid and sodium sulfate or sodium hydrogen sulfate are the byproducts. Other processes, which produce fewer byproducts, use hydrochloric acid, methanol, or hydrogen peroxide as the reducing agent. The advantage of hydrochloric acid is very low costs, but the amount of chlorine present as a byproduct in the chlorine dioxide can be rather high (about 20%). In bleaching this results in increased formation of undesired halogenated products. Nowadays the methanol and hydrogen peroxide processes are the most important. In these processes very pure chlorine dioxide is generated as a gas, highly diluted with air or water vapor to avoid explosions. It is absorbed in cold water to give a concentration of 6 – 12 g/L.

For reactions of ClO_2 with pulp a pH value between 2 and 5 is normal. Within this pH range chlorine dioxide does not affect the degree of polymerization of cellulose. Typical reaction temperature for chlorine dioxide is between 50 and 75 °C. In hardwood pulp bleaching it is favorable to start bleaching at very high temperature (> 90 °C), as this allows the simultaneous oxidation of lignin and hydrolysis of hexenuronic acids.

In bleaching textiles sodium chlorite [7775-09-9] is used as the source of chlorine dioxide. Hydrochloric acid, formic acid [64-18-6], or acetic acid [64-19-7] is used to liberate ClO_2.

$$5\,NaClO_2 + 4\,HCl \rightarrow 4\,ClO_2 + 2\,H_2O + 5\,NaCl$$

2.2.3. *Hydrogen Peroxide and Other Peroxo Compounds (* ⟶ Hydrogen Peroxide*;* ⟶ Peroxo Compounds, Inorganic*;* ⟶ Peroxy Compounds, Organic*)*

Hydrogen peroxide [7722-84-1] has been used as an industrial bleach since the early 1900s. At first the main use was bleaching textile fibers. Sodium perborate [7632-04-4], $NaBO_3 \cdot 4\,H_2O$, prepared from sodium peroxide and borax, was used in the laundry detergent Persil as a bleach as early as 1907. Even today, perborates and percarbonates are used in large quantities in laundry detergents. Their mild bleaching effect at elevated temperatures is gentler to fibers and therefore superior to that of the harsher hypochlorites, which are used as so-called cold bleaches. Because of the lower storage stability of pure percarbonate, specially coated products are applied.

Aqueous solutions of hydrogen peroxide are available in concentrations up to 90 wt %. Solutions with 35 – 70 wt % are generally applied in bleaching. The most important application of hydrogen peroxide is bleaching of pulp for paper production. Mechanical pulp and chemical pulp are bleached with alkaline peroxide solutions. Hydrogen peroxide is also used for bleaching textile fibers such as cotton, flax, wool, and synthetics.

Commercial processes use slightly to strongly alkaline conditions for hydrogen peroxide bleaching. Usually sodium hydroxide is the source of alkali. The initial reaction is the nucleophilic addition of hydroperoxide anions to carbonyl groups [7]. Therefore, the bleaching rate is increased by addition of alkali:

$$HOOH + OH^- \rightleftharpoons HOO^- + H_2O$$

However, alkaline conditions also favor side reactions like the disproportion of hydrogen peroxide into oxygen and water:

$$HOO^- + H_2O_2 \rightarrow H_2O + OH^- + O_2$$

The bleaching result depends on activation and stabilization. The reaction rate increases with temperature and alkali concentration. However, side reactions such as the thermal decomposition of hydrogen peroxide into radicals become more

likely or even dominant at high temperatures, which also lead to yield losses due to solubilization of the material being bleached. Consequently the normal temperature range for peroxide bleaching is between 60 and 90 °C.

Stabilization of the alkaline bleaching liquor may be required to minimize peroxide decomposition. Hydroxyl radicals, generated by the decomposition of peroxide, are highly unselective oxidizing agents that produce undesired side reactions. In chemical pulp bleaching the chelation of transition metals is only required in TCF bleaching. In ECF bleaching hydrogen peroxide typically is applied only following an acidic stage. This removes transition metals in the washing step. In mechanical pulp bleaching, detrimental metals are best removed by pretreatment with a chelating agent. Typical chelating agents are the sodium salts of diethylenetriaminepentaacetic acid (DTPA), ethylenediaminetetraacetic acid (EDTA), or the corresponding phosphonates, which have similar or even better chelating ability. In addition sodium silicate is applied as a stabilizer which buffers the bleaching liquor. Similarly, magnesium salts (mostly magnesium sulfate, Epsom salt) are used. The effect of the stabilizers is to precipitate or absorb detrimental compounds on colloidal silica or magnesium hydroxide.

In the bleaching process hydrogen peroxide cleaves side chains and destroys quinoid structures irreversibly. The oxidation and destruction of quinones is an important prerequisite for achieving good brightness stability. Peroxide-bleached products show lower reversion compared to other oxidants.

Peracetic acid [79-21-0], CH_3COOOH, is used in small amounts as an activation step prior to alkaline hydrogen peroxide treatment. Its application allows a higher brightness increase or a lower total consumption of bleaching chemicals. The reaction with pulp is conducted under mild acidic conditions; it is predominantly a hydroxylation reaction of the residual lignin. Peracetic acid is produced by mixing acetic acid and hydrogen peroxide. In the presence of a strong acid (e.g., sulfuric acid) an equilibrium between acetic acid, peracetic acid, hydrogen peroxide, and water is rapidly established. As the other compounds in the mixture do not contribute to the bleaching reaction of peracetic acid the application of equilibrium peracetic acid is expensive. An option to overcome this problem is the use of distilled peracetic acid. Vacuum distillation of equilibrium peracetic acid yields a rather pure peracetic acid solution in water. Distilled peracetic acid with a content of about 35 % in water should be stored only below 4 °C, because at higher temperature the equilibrium with hydrogen peroxide and acetic acid is again slowly established. An alternative is on-site mixing, which yields a peracetic acid/peroxide mixture which can be used for an initial peracetic reaction and a subsequent peroxide bleaching step. This is achieved by adding sufficient alkali after the acidic stage.

Peracetic acid is generated in situ from hydrogen peroxide and tetraacetylethylendiamine (TAED) [10543-57-4] under weakly alkaline conditions. This procedure is applied in laundering agents with percarbonate or perborate as peroxide source. It is also applicable in bleaching of specialties.

Potassium peroxosulfate [37222-66-5], $KHSO_5$, is used for bleaching polyamide and cellulose fibers. However, it is ordinarily used only to clean wool and to reduce its shrinkage. Sodium peroxodisulfate [7775-27-1], $Na_2S_2O_8$, and ammonium peroxodisulfate [7727-54-0], $(NH_4)_2S_2O_8$, are used to desize cotton and sometimes as an additive in hydrogen peroxide bleaching.

2.2.4. *Ozone (⟶ Ozone)*

Ozone [10028-15-6] is produced from oxygen by silent electrical discharge. For bleaching pulp, ozone is typically produced from pure oxygen. This allows a high ozone concentration in the gas (up to 12 wt %) and facilitates the mixing procedure. Ozone is used at a pH below 4. Temperature in ozonation must be kept below about 50 °C to avoid side reactions with the cellulose caused by the high oxidation potential. At too high a temperature brightness is less stable and yellowing takes place easily.

2.2.5. *Chlorine and Hypochlorites (⟶ Chlorine)*

In the past chlorine [7782-50-5] was widely used in chemical pulp bleaching for lignin oxidation (delignification). In chlorination substitution and oxidation of the aromatic rings in lignin takes place, producing dicarboxylic acid and chlorinated lignin fragments [7]. About 10 % of the applied chlorine is found as halogenated compounds in the effluent. Chlorinated phenols and polyhalogenated dibenzodioxins and dibenzofurans are among these products. Quantitative analysis of these compounds is performed by an extractive method with activated carbon, and the result is expressed as adsorbable halogenated organic compounds (AOX) [8]. Some of these compounds are mutagenic [9]. In most regions of the world the application of chlorine was phased out shortly after identification of these compounds in the effluent.

Today hypochlorite is used mainly as stain remover (“cold bleach” in laundering). Like chlorine, it is no longer applied on a large scale in chemical pulp bleaching. There application is limited to the use of very small amounts for controlled lowering of the degree of polymerization of dissolving pulp. The oxidation potential of hypochloric acid [7790-902-3], HOCl, is higher (+ 1.50 V) than that of chlorine (+ 1.35 V) or hypochlorite [14380-61-1] OCl^- (+ 0.94 V). To avoid side reactions (mainly depolymerization) involving the aggressive hypochloric acid, bleaching is carried out in alkaline solutions to minimize the concentration of undissociated hypochloric acid. Because the hypochlorite anion is only a weak nucleophile, unable to attack electron-rich aromatic systems, alkaline conditions cause fewer unfavorable side reactions. Bleaching with hypochlorite generates halogenated compounds in side reactions. However, in comparison to chlorine AOX formation is significantly lower. Chloroform is the main byproduct. Sodium hypochlorite [7681-52-9] solutions are commercially available with active chlorine concentrations of 150 – 160 g/L. Active chlorine is the amount of chlorine set free upon acidification of the hypochlorite solution.

2.3. Reducing Agents

The most important reducing bleaching agent is sodium dithionite. Sulfur dioxide has been used to bleach wool since ancient times, but it is of less importance today. Sulfinic acid derivatives are used mainly for the removal of colorants from textile fabrics.

2.3.1. *Sodium Dithionite (* ⟶ Sulfites, Thiosulfates, and Dithionites*)*

Sodium dithionite [7631-94-9], $Na_2S_2O_4$, is still known as hydrosulfite in North America, although this incorrect initial description was recognized and corrected as early as 1881. Sodium dithionite is today produced from sodium formate and sulfur dioxide. Zinc dithionite [13986-17-9], prepared from sulfur dioxide and zinc dust, was formerly more important than the sodium salt. However, the heavy metal zinc causes environmental problems, and today on-site production of zinc dithionite is no longer practiced. The same applies for production from sodium amalgam and sulfur dioxide. On-site generation of dithionite from alkaline sodium borohydride solution, sodium bisulfite, and sulfur dioxide is used by some paper mills.

Sodium dithionite is available as crystalline powder (90 % $Na_2S_2O_4$) or as a refrigerated 150 g/L solution stabilized with alkali. Solutions should be kept well below 10 °C because dithionite disproportionates to thiosulfate and bisulfite:

$$2\,S_2O_4^{2-} + H_2O \rightarrow S_2O_3^{2-} + 2\,HSO_3^{2-}$$

Dithionite destroys chromophores by reducing carbonyl groups to alcohols and quinones to phenols. It is used to bleach mechanical pulp, wool, silk, bristle, hair, straw, soap, glue, kaolin, and foods such as sugar, molasses, gelatin, and edible fats.

Dithionite is easily oxidized to sulfite and sulfate by oxygen. The solution decomposes at elevated temperatures to thiosulfate, sulfite, hydrogen sulfide, or sulfur, the exact products depending mostly on pH. The pH selected for bleaching with dithionite is a compromise between the most effective bleaching and the lowest loss of dithionite. Normally, a pH of 5 – 6 and temperatures of 50 – 80 °C give the best results. In mechanical pulp bleaching, hydrogen peroxide and dithionite bleaching are often combined in two sequential steps.

2.3.2. *Sulfur Dioxide (* ⟶ Sulfur Dioxide*)*

Sulfur dioxide [7446-09-5] is used mostly in the form of sodium hydrogensulfite, $NaHSO_3$. Because of the relatively poor bleaching effect, SO_2 is no longer widely used. It can be applied in mechanical pulp production as a pretreatment to dithionite bleaching. Another use is the treatment of wool.

2.3.3. *Sulfinic Acid Derivatives (* ⟶ Sulfinic Acids and Derivatives*)*

The important sulfinic acid derivatives are sodium hydroxymethanesulfinate [149-44-0]

and formamidinesulfinic acid [4189-44-0]

Hydroxymethanesulfinates are prepared by treating dithionites with formaldehyde; they are more stable than the dithionites. Higher temperatures are needed to produce the full reducing power. These sulfinic acid derivatives are therefore used in processes that operate above 75 °C, in which dithionite would be decomposed rapidly. They are used for bleaching soap, glue, gelatin, and fatty acids. However, their main use is in dyeing processes.

Formamidinesulfinic acid is prepared from thiourea and hydrogen peroxide. Therefore, it is sometimes called thiourea dioxide. It is a poorly water soluble crystalline product. It becomes more soluble under alkaline conditions, and it reaches its highest reducing power above 80 °C. It is used to increase brightness of textiles and to remove dyes from fabrics (like hydroxymethanesulfinic acid). Its strong reducing power at high temperature favors application in bleaching of secondary fibers in the dispersing step. It is very effective in the destruction of colorants used for colored paper. By volume this is the most important application.

[Top of Page]

3. Enzymes

The technical use of enzymes in bleaching is still the exception. The discovery of lignin-degrading enzymes in white rot fungi (*Phanerochaete chrysosporium*) [10] seemed to open a new option for industrial-scale delignification and bleaching. However, the reaction was very slow, not selective enough, and the enzyme required coenzymes which degraded cellulose. This is a general problem of enzyme application. Enzyme strains must be very pure to avoid negative side reactions by activity of other enzymes. In addition many industrial processes are operated at elevated temperature or extreme pH. Both require the use of adapted enzymes. Thermophilic organisms are a preferred source for the selection of an enzyme.

Xylanases are used to eliminate part of the precipitated xylan from unbleached kraft pulps [10]. This treatment lowers the demand for chlorine dioxide in ECF bleaching by approximately 10 %. It is suggested that lignin on the fibers is partly covered by precipitated xylan, and that removal of the xylan allows this lignin to be washed off more easily. The overall moderate effect has made xylanase application a niche option for pulp mills with limited availability of chlorine dioxide.

Laccase is the enzyme that polymerizes the phenylpropane units in plants and produces the lignin polymer. With the aid of a mediator, laccase can be used for the delignification of pulp [11]. Mediators are easily converted to radical cations by reaction

with laccase and oxygen. The intermediate product oxidizes the lignin. Theoretically, the mediator, for example, *N*-hydroxybenzotriazole [2592-95-2], can be reoxidized several times by the enzyme. However, repeated reaction is the exception. Consequently, demand for the mediator is high. Currently (in 2006), industrial application is not economical.

Cellulases are used to soften cotton fabric. They are applied in the stone washing of jeans as a substitute for the mechanical effect of pumice stones. This effect on the surface of the fabric causes a fading of the color, because the colorant is located only on the fiber surface.

Cellulases have also been recommended for improving the fiber strength of wastepaper pulp. The dissolution of fines and fibrils increases the average fiber length and increases the strength potential. However, this solubilization lowers yield and increases the effluent load. Therefore, large-scale application remains unlikely.

[Top of Page]

4. Bleaching Processes

The bleaching processes for the substances in Table 2 are described in detail in the articles on the substances. (For example, ⟶ Paper and Pulp.) The bleaching processes for pulp and textiles, the most important uses economically, are briefly summarized here.

4.1. Pulp (⟶ Paper and Pulp)

Fibers used for paper production are predominantly bleached [2]. A distinction can be made between the main types of paper fibers: chemical pulp and mechanical pulp. Wastepaper typically is a mixture of both types of fibers and contains in addition fillers such as china clay and calcium carbonate and printing ink.

4.1.1. *Chemical Pulp*

The most important method for the production of chemical pulp is the alkaline *kraft* or sulfate process, which is by far the dominant process worldwide. The acidic *sulfite* process plays a very minor role with a production share below 5 %. An oxidative process is required to destroy the residual lignin polymer. Because each bleaching agent has its specific advantages and disadvantages, generally several chemicals are applied in a sequence of steps. Bleaching is carried out continuously in towers or reactors. Between the steps, washing is carried out in drum, belt, displacement, press or diffusion washers. The bleachability of a pulp depends upon the pulping procedure. In general, kraft pulps require more effort and more bleaching steps to reach very high brightness. Typical market pulp brightness for softwood pulp is > 88 % ISO. The brightening process requires between four and six stages. Hardwood pulp is available with a brightness of 90 % ISO and higher. The abbreviations used to describe a bleaching sequence are listed in Table 3.

Table 3. Bleaching stage designations, conditions, and effects

Designation	Conditions and effects
O	oxygen stage for oxidation of lignin with molecular oxygen under alkaline conditions at 90 – 100°C.
A	acid stage to remove transition metals (at 40 – 60°C) or hexenuronic acid (at > 90° C) by hydrolysis; the acid typically is sulfuric acid.
Q	acidic stage (pH 5 – 6.5) with chelating agents (e.g., EDTA or DTPA) for transition metals removal.
D	chlorine dioxide stage using a solution of ClO_2 at pH < 5 in water for lignin oxidation.
E	extraction stage using caustic soda for solubilization of oxidized lignin (pH 9.5 – 11).
Eo	extraction with addition of oxygen gas for improved lignin removal by oxidation.
Eop	extraction reinforced with oxygen and hydrogen peroxide for improved lignin removal by oxidation and brightening.
P	alkaline bleaching stage with hydrogen peroxide, (pH >10 – 11, 60 – 90 °C).
OP	pressurized peroxide stage with addition of oxygen, potentially operated above 100 ° C with up to 0.3 MPa pressure.
Z	delignification stage with gaseous ozone.
Paa	weakly acidic stage (pH 5) with peracetic acid for lignin oxidation and activation for subsequent P stage.
X	enzyme treatment stage with xylanase or other hemicellulases to improve lignin accessibility by removal of precipitated carbohydrates.
Y	reductive treatment with dithionite.
N	neutralization.

Bleaching sequences are described by a sequence of these letters, e.g, ODED. In this combination the washing procedure between the stages is not explicitly mentioned. A combination without intermediate washing can be indicated by the use of brackets, e.g., (ZD). The way of combining the letters is not standardized. Sometimes in a combination of letters the capital letter is used to describe the main purpose of the stage; the combination “Eo” stands for an extraction stage with a support of the extraction by oxygen addition. Sometimes the description EO is used for the same purpose. A glossary of bleaching

terms is available in [12].

In the past in chemical-pulp bleaching chlorine was used as the main delignification chemical (abbreviated by C). Its selectivity in lignin oxidation and the low level of side reactions with cellulose made it the preferred delignification compound for some decades. A serious disadvantage is the generation of a large amount of various halogenated compounds with limited biodegradability. The detection of highly halogenated dioxins and furans initiated the elimination of chlorine from pulp bleaching. Its application today in pulp bleaching is limited to small, old pulp mills in exotic regions. Current bleaching processes use basically two alternative approaches: The replacement of chlorine by dominantly chlorine dioxide is labeled as ECF (elemental chlorine free) bleaching. Total chlorine free (TCF) bleaching requires a complete change in technology. TCF bleaching uses mainly oxygen and hydrogen peroxide for bleaching. Ozone or peracetic acid is in addition required to achieve high brightness. In ECF bleaching the simplest approach is to just exchange chlorine with chlorine dioxide. The optimization of an ECF sequence requires additional changes: higher temperature in the D stage and the reinforcement of the extraction stages with oxygen and hydrogen peroxide. ECF “light” is a label used to describe a sequence using less chlorine dioxide and more hydrogen peroxide.

Typical industrial bleaching sequences are listed in Table 4.

Table 4. Chemical pulp bleaching sequences

Pulp type	Bleaching process sequence	
Kraft pulp, softwood	ECF	ODEopDEpD, ODEoDnD
Kraft pulp, softwood	ECF “light”	OQ(OP)DP
Kraft pulp, softwood	TCF	OQ(OP)QPP, OOQ(OP)PaaP
Kraft pulp, hardwood	ECF	$OD_{(hot)}$EopDP, O(ZE)DP
Kraft pulp, hardwood	TCF	OQPPP
Sulfite pulp	TCF	OQP, OQ(PaaP), EopP

In bleaching kraft pulp, oxygen is used to decrease the amount of residual lignin without loss of viscosity and strength. Because kraft pulping and oxygen delignification both use sodium hydroxide as alkali source, combined evaporation and recovery of the effluents from pulping and oxygen delignification is possible. Thus, oxygen delignification not only decreases the amount of bleaching chemical required, it also lowers the overall effluent load. Oxygen delignification has become the standard measure for lowering the lignin level after pulping. Softwood kraft pulp can be further delignified by more than 50 %, and hardwood pulp by nearly 40 %.

The changes in bleaching technology have resulted in significantly lower levels of halogenated compounds in the effluent of pulp bleaching. These compounds are determined as AOX (adsorbable organic halogenated compounds). Historically the amount of AOX discharged per tonne of pulp could be higher than 5 kg/t. Most countries have set narrow limits to the discharge of AOX. ECF bleaching allows staying within these limits as it generates much less halogenated compounds, which show in addition improved biodegradability.

Combination of two bleaching chemicals in one stage is sometimes possible and advantageous. The effects of oxygen and hydrogen peroxide, for example, are to a certain extent additive. Chlorine dioxide and ozone can be applied in one combined step by using two mixers in line.

Water consumption in pulp production has decreased significantly. Volumes declined from more than 50 m^3/t to about 15 m^3/t in modern pulp mills. The limitation to further decreases is the presence of “nonprocess elements” in wood. The recovery of the process chemicals in parallel results in an increase of the concentration of these elements in the system. Therefore, discharge of effluent or solids will still be necessary. The cations are predominantly traces of metals such as Ca, Mg, Fe, Mn, and Cu. Chloride and sulfate are the main counterions. The target of process improvements is to minimize the impact not only of the discharge of liquid effluent but also to decrease atmospheric emissions and the amount of solid waste disposed of in landfills.

Bleaching chemicals are typically applied under medium-consistency conditions, that is, a fiber/water ratio of 1/9 to 1/11. This relatively thick mixture is fluidized by special pumps and pressed through upflow towers.

Typical market pulp brightness for ECF softwood pulp is 88 – 90 % ISO. Hardwood pulp is sold at a brightness of 90+ % ISO. Specialties such as photo paper can have a brightness > 92 % ISO. Lower brightness can be sufficient for a wide number of applications in papermaking and tissue production, and thus brightness varies over a wide range from unbleached to semibleached to fully bleached pulp. Typically TCF pulp is available with more brightness variation to balance brightness requirements and fiber strength properties. In TCF bleaching it is more difficult to simultaneously obtain top brightness and top fiber strength.

Special paper grades such as bank notes, cigarette papers, and tea bags are produced from special fibers. Esparto grass, hemp, flax, kenaf, ramie, and abaca are applied, as well as cotton linters. Although not all these fibers can be bleached to very high brightness, the requirement for bleaching chemical is low, and only short bleaching sequences are necessary. Another group of annual fiber plants includes the cereals, especially rice straw, bamboo, and depithed bagasse. They are used as a raw material for chemical or mechanical pulp.

4.1.2. *Mechanical Pulp*

Grinding tree trunks on rotating grinder stones is the traditional method of preparing mechanical pulp. The abbreviation describing this process is GW (groundwood) or PGW (pressurized groundwood) for processes operated at 2 – 3 bar. Today rotating metal disks, refiners, and wood chips as raw material are widely used; the conventional groundwood process has been phased out because of its high requirement for workforce. There are several slightly different processes: refiner mechanical pulp (RMP), thermomechanical pulp (TMP), chemothermomechanical pulp (CTMP), and alkaline peroxide mechanical pulp (APMP). In all cases, the amount of lignin in the pulp is reduced only slightly. At high temperature internal bonding within the wood chips decreases and longer fibers result from the mechanical action. Pretreatment of the wood chips with sodium sulfite, caustic soda (applied to softwood, e.g., spruce) or alkaline hydrogen peroxide (typically applied to hardwoods such as aspen or poplar) yields a defiberized product with even longer fibers.

The use of strong oxidizing agents such as oxygen or chlorine dioxide for bleaching mechanical pulp would result in an enormous consumption of chemicals and significantly lower the yield, because these chemicals would oxidize and dissolve the lignin present in the pulp. Hydrogen peroxide is used because it predominantly destroys chromophores without attacking the aromatic rings of lignin [7], so that yield losses are moderate. The amount of dissolved wood material depends on the intensity of bleaching; the more peroxide is applied, the more alkali is required for its activation, and in turn more organic material is dissolved. A simple possibility for a moderate increase in brightness is reductive treatment with sodium dithionite. This chemical can be added already during the refining process.

The maximum possible increase in brightness is lower for mechanical pulps than for chemical pulp. Softwood mechanical pulp can be bleached with dithionite to 70 – 75 % ISO. Hardwoods such as poplar and aspen bleach more easily, as their lignin contents are lower. Thermomechanical pulps give lower brightness increases, because the chromophores produced by high-temperature treatment are more stable towards reduction. Hydrogen peroxide bleaching produces higher brightness levels: softwood pulp can be bleached to 75 – 80 % ISO. Hardwoods mechanical pulp can reach brightness levels of up to 85 % ISO.

Hydrogen peroxide bleaching is best conducted at high pulp consistency, preferably above 30 %. At high consistency the relative concentration of the bleaching chemical is higher, and side reactions with organic compounds dissolved in the water are avoided. Bleaching processes are run continuously in downflow towers. Reductive dithionite bleaching is carried out conventionally at lower consistencies (4 – 6 %) in upflow towers to avoid consumption of the reducing agent by atmospheric oxygen. Deaeration in modern medium-consistency pumps allows reductive bleaching to be carried out at medium consistency (ca. 10 %) in upflow towers.

4.1.3. *Paper Recycling (Deinking)*

The amount of wastepaper recycled with a deinking step is continuously increasing. The aim of deinking is the removal of printing ink and other impurities from the fibers. Typically, printing inks cannot be bleached, as they consist mainly of pigments like carbon black and hydrophobic polymers. These inks must be removed mechanically. There are two major processes: washing and froth flotation [13]. For froth flotation, repulping is carried out under alkaline conditions with the addition of a sodium soap. The ink is detached and collected on precipitated calcium soap particles. The flotation of these precipitates removes not only ink particles but also other impurities. The addition of hydrogen peroxide prevents alkaline yellowing and improves brightness. As another additive sodium silicate is applied. It improves ink separation and suppresses the coflotation of fillers and fines. For best brightness and highest yield all four chemicals — caustic soda, soap, hydrogen peroxide, and sodium silicate — are required.

For deinking by washing, repulping of the wastepaper can be performed under alkaline or neutral conditions. To facilitate ink detachment surfactants or soaps are added. The washing process removes ink, fillers, and fines simultaneously. It is therefore the preferred method for the use of secondary fiber in tissue production.

Today the majority of recovered fibers subjected to a deinking process are used in newsprint production, where up to 100 % of the final product can be recycled paper. In smaller amounts deinked wastepaper is used as furnish in higher quality paper grades, such as SC (supercalendered) paper, copy paper, or printing and writing grades. Higher quality wastepaper (e.g., mixed office wastepaper) is used for the production of tissue paper grades. Brightening, especially the removal of dyes from colored paper grades, includes a combination of reductive and oxidative bleaching with formamidine sulfinic acid and hydrogen peroxide. A typical North American development is deinked market pulp of very high brightness. The intention of the recovery procedures is to achieve a fiber quality close to short-fiber chemical pulp. This requires a multistage process, including flotation, washing, and bleaching. The raw material generally is mixed office wastepaper. Bleaching stages include oxygen, hydrogen peroxide, and sodium dithionite or formamidine sulfinic acid. In some mills hypochlorite is still used. A higher content of mechanical fiber in such a process is difficult to handle, as oxygen delignification dissolves most of the fiber material and, in parallel to the loss of yield, a very high effluent load is generated.

4.1.4. *Environmental Aspects of Pulp Bleaching*

Bleaching removes part of the product being bleached. Washing is the most important method for removing the oxidized or reduced compounds and causes an effluent load which can be expressed as BOD or COD, or TOC (total organic carbon). Authorities normally set limits to the discharge of biodegradable compounds and oxidizable material. Treating the effluent starts with a “primary” step, the sedimentation of suspended solids (e.g., fibers). The standard method for removing organic material from the effluent in kraft pulp mills is biological treatment in aerated lagoons. This is denoted “secondary” treatment. The degradation of organic material with bacteria requires oxygen. Energy demand for aeration is about 1 kW·h/kg BOD_5 [14]. About half of the organic material is transformed into carbon dioxide, and the other half becomes biomass and must be separated as sludge. Sludge dewatering and disposal or combustion cause additional costs. An attractive alternative is an anaerobic fermentation step. This conversion leaves only about 5 % of the organic matter as residue for disposal. All other organic material is converted to biogas, mostly methane. Typically the BOD is decreased by more than 90 %. Anaerobic and aerobic treatment can be combined in two successive stages starting with the anaerobic treatment. The excess sludge from the aerobic stage can be recycled into the anaerobic stage. A “tertiary” treatment is the final precipitation of remaining suspended or dissolved compounds with chemical coagulation. Usually, compounds for such a treatment are aluminum salts, Fe^{III} salts, and lime slurries. Tertiary treatment is mainly applied to remove excess nutrients like phosphorous, but it can also

remove COD and AOX.

In ECF bleaching halogenated compounds are produced during the bleaching reaction. Because of the wide range of halogenated products, the use of a sum parameter is widely accepted to characterize the amount. A standard method is AOX analysis, which describes the amount of adsorbable (on activated carbon) halogenated compounds [8]. Conventional bleaching resulted in AOX amounts of 5 – 8 kg/t of organically bound chlorine. ECF conditions can lower the AOX discharge from the bleaching plant to less then 1 kg. A further decrease is achieved in biological treatment, which can cut the AOX level by more than 50 %.

The bleaching process leaves residual halogenated organic compounds in the pulp, which are measured as organic halogen (OX) in pulp. To a certain extent it is possible to identify the bleaching process applied by measuring the residual OX content of a pulp sample. ECF bleaching has residual OX contents between 150 and 30 g/t. This lower level is also the accepted level for TCF bleached pulp, because the pulp can have a natural background content of halogenated compounds and a higher level of chloride ions in pulp during bleaching can generate residual OX even with TCF bleaching.

In chemical pulp production specific water consumption is below about 30 m^3/t . A further decrease to less than 15 m^3/t is achieved with sophisticated washing equipment and countercurrent waterflow [15]. Complete bleach plant closure is very difficult to achieve. Most units labeled as “closed” in reality are still consuming water. One reason are the “nonprocess” elements present in wood. They become concentrated in the recovery loops and can cause equipment scaling or even upset the recovery procedure. The inclusion of bleach plant effluent in the recovery process increases scaling and corrosion potential. Consequently “closed” mills use “kidneys” to eliminate troublesome substances. Such purging consumes water or requires the disposal of solid waste after evaporation and combustion. (Solid waste would contain salts of the nonprocess elements and salts resulting from pulping and bleaching chemical application).

Totally effluent free bleaching only changes the kind of discharge: from water pollution to air pollution or to the need for solid waste disposal. The concentration process required (evaporation) will increase energy demand.

4.2. Textile Fibers (⟶ Textile Dyeing)

The quality of the raw material dictates the potential for a simple or a more complicated bleaching procedure. The higher the level of impurities in the material to be bleached, the more steps are required. Natural products like cotton, flax, and wool can be heavily contaminated with sand and other dirt. Washing in the presence of acid or chelating agents may be required to achieve good results in the bleaching stage.

Cotton, the most important natural fiber, is usually bleached with hydrogen peroxide because alkaline oxidation not only increases brightness but also removes extractives, saponifiable waxes, and pectins, and destroys the lignin of residual seed capsules. In the peroxide stage, chelating agents, magnesium salts, and sodium silicate are added to prevent transition metal catalyzed destruction of the cellulose.

Cotton linters are used as a specialty fiber for papermaking and as raw material for cellulose derivatives like cellulose acetate. Linters are normally alkaline pretreated and then bleached in several stages, for example, in a chlorine dioxide – hydrogen peroxide – chlorine dioxide sequence, analogous to chemical pulp bleaching.

Flax is the source plant for linen. Bleaching of flax is very similar to that of other plants containing bast fibers, for example, hemp or ramie. Because of the low lignin content a pulping process is not required. Most of the impurities can be removed by mechanical action. High brightness and cleanliness is achieved with multistage processes using a hot alkaline pretreatment followed by sodium chlorite and hydrogen peroxide.

Wool needs thorough washing after shearing. The scouring step removes sand and other dirt and separates lanolin (wool fat). Wool is a keratin (protein) fiber and thus sensitive to alkaline treatment. Hydrogen peroxide bleaching must be carried out at low temperature and below pH 8, often under neutral to even slightly acidic conditions. As a result the bleaching times are long and the potential for high brightness is limited. Combining oxidative peroxide treatment and reductive dithionite treatment gives the greatest increase in brightness.

Synthetic fibers like rayon are bleached with hydrogen peroxide or hypochlorite. Because polyurethane is sensitive to chlorinating chemicals, polyurethane fibers are bleached only with hydrogen peroxide. Polyamides, polyesters, and polyacrylonitriles are bleached with sodium chlorite. Hot alkaline hydrogen peroxide may cause polyamides to lose strength.

4.3. Other Products

Animal Products. Similar to wool hair and bristle are bleached with semineutral or slightly alkaline peroxide.

Mother-of-pearl, ivory, and bones are bleached with hydrogen peroxide solutions, which are stabilized with either sodium diphosphate in weak alkaline medium or sodium silicate, possibly in the presence of ammonia. Bones and ivory are bleached at room temperature for an extended time.

Vegetable Products. *Straw* is bleached with alkaline hydrogen peroxide. Straw-hat bleaching was the first important application for sodium peroxide at the beginning of the 1900s. Exotic straws such as pandan straw or bamboo grass require bleaching with sodium chlorite. The bleached products are typically used by florists.

Peeled rattan reeds, which are used for wicker baskets and furniture, are brightened with hydrogen peroxide (buffered with sodium carbonate and silicate) at ambient temperature and a dithionite stage.

Wood veneer and *wood* are bleached with hydrogen peroxide and ammonium carbamate. Offcolors can be corrected with this treatment, which is important in furniture production.

Palm oil and other *vegetable oils* for food and chemical production need to be purified before use. They are typically bleached not by a chemical reaction but by adsorption of colored impurities. High surface area clays (aluminum or magnesium silicates) are added at elevated temperature. Filtration is used for separation. The same procedure is applied for *paraffins* and *waxes*. Disposal of the clay contaminated with oil and colored material can become an environmental challenge.

Inorganic Products. *Clays* are bleached as aqueous slurries with sodium dithionite to remove the color resulting from metal ions such as iron. The reduced metal (Fe^{2+}) is washed off.

Technical-grade *sulfuric acid* is bleached with hydrogen peroxide. The oxidation of organic impurities takes place via the intermediate generation of Caro's acid (H_2SO_5).

5. Economic Aspects

Blood is a multifunctional transport medium of vital importance for the body of higher organisms. Its composition is very complex and includes various cell systems with peculiar functions, proteins, electrolytes, metabolites, and highly sophisticated mediator systems. Both cells and plasma, which can be separated by centrifugation, can be used as and further processed into medicines. Serum is the fluid remaining after coagulation of the blood. In this review, blood cell systems and plasma proteins are referred to and medicinal aspects including blood and plasma collection and processing are described. The medicines derived from blood and plasma, as well as basic research and clinical trials should keep an important place because of the medicine as a whole benefits extremely from transfusions and, in particular, hemophiliacs gain an enormous improvement of life quality and life expectancy.

1. Introduction

Blood is a multifunctional transport medium of vital importance for the body of higher organisms. The composition of blood is very complex and includes various cell systems with peculiar functions, proteins, electrolytes, metabolites, and highly sophisticated mediator systems. Its undisturbed circulation in an ubiquitous system of blood vessels with fine ramifications throughout the whole organism, connections to the lymph vessels and interfaces with the extravascular compartments is essential for the performance of all organs and enables numerous exchange processes. A sudden stop of blood circulation will cause the death of the organism within a short time. The functions of blood can be allocated to the following categories:

1. *Respiratory function*: the blood provides the capacity to transport oxygen needed for the energy metabolism from the lung to the organs, and of carbon dioxide back to the lung.
2. *Regulatory function*: besides by the nervous system, numerous specific body functions are controlled or influenced by messenger substances such as hormones or cytokins that are transported by the blood; the production of blood cells itself is a good example (see Section Hematopoiesis, Stem Cells). The blood has to provide also a stable internal milieu; the pH is maintained within a narrow range around 7.4 by buffer substances and by transport of acid or basic substances to metabolic or excretory organs. The blood is also involved in the regulation of further important parameters, e.g., water household or temperature.
3. *Nutritive and metabolic function*: nutrients absorbed from the gastrointestinal tract are collected into the splanchnic vessels, transported via the portal vein to the liver, the body's main synthetic and storage organ, and further transferred to the tissues in order to maintain energy supply and their specific metabolic functions. Waste and toxic products, as well as superfluous water and electrolytes are transported from the tissues to the sites of their elimination.
4. *Protective function*: the human body is permanently subject to external and internal attacks of agents disturbing its homeostasis or even threatening the individual's life. The blood contains highly specialized cellular (various types of phagocyte cells and lymphocytes) and humoral (e.g., immunoglobulins, complement, proteases, and inhibitors) protective systems providing effective surveillance, defense, and repair.

The blood volume in humans is equivalent to about 6 to 8 % of the total body mass, which again underlines the significance of this “fluid organ”.

[Top of Page]

2. Composition, Physiology and Chemical Properties of Blood

Blood can be obtained by donation into special containers that contain substances preventing coagulation and can be easily separated by centrifugation into the cellular fraction and the liquid supernatant (the *plasma*); *serum* is the fluid remaining after blood has undergone coagulation. Both cells and plasma can be used and further processed into medicines. Blood cell counts and other relevant values are shown in Table 1.

Table 1. Typical values of selected cellular parameters measured in normal adult blood*; (Units are given as usually used in clinical laboratories and text books; in some countries and publications SI-units are preferred for certain parameters. The actual reference ranges may vary depending on the assay methods)

Parameter	Value	Remarks
Red cells		
Erythrocyte (red cell) count	m: 4.4 – 6.0 × 10^6/µL f: 4.2 – 5.5 × 10^6/µL	
Hemoglobin	m: 14.0 – 18.0 g/dL f: 12.0 – 16.0 g/dL	
Hematocrit (ratio cell volume:/ total blood volume)	m: 0.40 – 0.54 f: 0.37 – 0.47	
MCH (mean corpuscular hemoglobin)	27 – 32 pg	mean hemoglobin mass per single red cell
MCHC (mean corpuscular hemoglobin concentration)	32 – 36 g/dL	mean hemoglobin concentration in a single red cell
MCV (mean corpuscular volume)	80 – 94 fL	

Reticulocytes	7 – 15 per 10^3 red cells	
White cells		
Total white cell count	4.3 – 10.0 × 10^3/µL	
Differential white cell count (relative to total number):		values obtained with microscopy of blood smears; values with automatic counters may be different
Neutrophils, band form	1 – 5 %	
Neutrophils, segmented	45 – 70 %	
Eosinophils	1 – 4 %	
Basophils	0 – 1 %	
Monocytes	2 – 8 %	
Lymphocytes	20 – 40 %	
Platelets		
Thrombocyte count	150 – 350 × 10^3/µL	

* m = male, f = female proband.

2.1. Blood Cells

Several highly differentiated cell systems with specialized characteristics and functions are circulating in the blood. The cells may be either nucleated such as leukocytes, in this case they are reactive to various stimuli, and actively mobile between blood stream and tissues. Otherwise they are nonnucleated, have a restricted metabolism, and stay within the blood their whole life-span. An example of the latter category are erythrocytes.

2.1.1. *Hematopoiesis, Stem Cells*

After the fetal period, the production of blood cells (hematopoiesis) takes place essentially in the red bone marrow within spongious bones (e.g., vertebrae, sternum, pelvis), and in case of lymphatic cells also in lymph nodes and other sites (e.g., spleen, tonsils, appendix, Peyer's plaques, or during childhood in the thymus). In adults, the hematopoietic marrow has a total mass of about 1000 to 1200 g and thus belongs to the largest organs. It possesses a special microenvironment, a “matrix” of cells, connective tissue and adhesion proteins, which supports homing, proliferation, and maturation of hematopoietic cells. There is a permanent turnover of mature blood cells, and the half lives of several types are short. Therefore, great quantities of new cells have to be produced: for a healthy adult, the estimate is about 10^{11} granulocytes, 2 × 10^{11} erythrocytes, and 2 × 10^{11} thrombocytes every day.

The microscopic examination of bone marrow is a very important feature in the diagnosis of many hematological disorders. Specimens can be obtained by needle biopsy from the pelvis (*spina iliaca posterior*) for histology, or by puncture and aspiration from the sternum, and subsequent preparation of smears for cytological examination. The specimen can be stained using conventional panoptic dyes or specific antibodies in order to visualize certain markers or structures. The bone marrow gives at first glance the impression of a colorful, somewhat “chaotic” conglomerate of various cells of different size and appearance (Fig. 1). However, the hematopoiesis is a complex and very thoroughly regulated process, which is effectively controlled and can be adapted within a wide range to the actual needs of the organism in case of stressing situations such as infections or blood loss.

Figure 1. Bone marrow (overview)

Panoptic Pappenheim stain (same stain used also in Figs. 3-5) of a smear of a punctate obtained by sternal puncture and aspiration.

For the photographs in Figures 1 and 3-5, the authors are indebted to Mrs. Elke Eckstein, Philipps University Hospitals, Marburg, Germany.

The proliferating and differentiating bone marrow cells can be divided into several lineages, according to the resulting mature blood cells: (1) the “myeloid” lineages including the erythrocyte, thrombocyte, granulocyte of different types (neutrophil, eosinophil, basophil), and monocyte/macrophage precursors, and (2) the lymphatic cell lines. All of these cell lineages are ultimately derived from a common origin, the so-called *“pluripotent stem cells”* (Fig. 2). The latter are permanently proliferating in order to maintain a constant pool of pluripotent stem cells and to produce a sufficient number of progenitor cells for blood cell supply. Some stem and progenitor cells are permanently recirculated via the blood stream, which provides the opportunity to harvest them for therapeutic purposes by apheresis. The first step of hematopoiesis is the evolution into the myeloid or the lymphoid stem cells, and further into committed stem cells, which can be viewed as the start of the several lineages. By proliferation and progressive differentiation numerous cells at different stages are generated, until the cells reach the mature functional stage of blood cells and enter the blood via the ample bone marrow vessels (sinusoids). While pluripotent and committed stems cells can not be discriminated by morphology, but only by specific surface antigens (used as diagnostic markers), the more differentiated bone marrow cells can be identified by their typical microscopic appearance. There are, e.g., progenitors of erythrocytes (*erythroblasts*, Fig. 3), granulocytes (*myeloblasts*, Fig. 4), or thrombocytes (*megakaryocytes*, Fig. 5).

Figure 2. Scheme of cell line differentiation in hematopoiesis

BFU = burst-forming unit; E = erythrocyte; Epo = Erythropoetin; Eo = Eosinophil; GM = granulocyte-macrophage; MEG = Megakaryocyte; Tpo = Thrombopoetin.

Figure 3. Erythropoiesis:

Large cell in the center is a proerythroblast; during further divisions and differentiation the cells become smaller, the nuclei increasingly dense, the cytoplasm contains more and more hemoglobin. Finally, the nucleus is extruded. At the left neutrophil granulocyte.

Figure 4. Myelopoiesis:

Figure 5. Megakaryocytes:

Largest cells in bone marrow (compare surrounding cells)

A) Mature megakaryocyte with giant nucleus and “granulation”; B) megakaryocyte after shedding of platelets, leaving nucleus behind.

The proliferation and differentiation of the lineages is controlled specifically by hematopoietic growth factors, which belong to an important group of substances referred to as cytokins or “biologic response modifiers”. Their nomenclature is somewhat confusing, due to historical reasons. A long-known substance is erythropoietin, a polypeptide produced by the kidneys in response to reduced oxygen concentration, which stimulates the production of oxygen carriers, i.e., erythrocytes. A rather “new” growth factor is thrombopoietin, which stimulates megakaryocytes [1], and shows about 50 % homology to erythropoietin. Other factors were discovered by their ability to promote in vitro the growth of progenitor cell colonies, which led to a nomenclature of the responsible cells as *colony forming units* (CFU) and of the growth factors as *colony stimulating factors* (CSF), for example the granulocyte-colony stimulating factor, G-CSF. It was also noted that several of a group of substances discovered as leukocyte-derived modifiers of inflammation, the interleukins, are also hematopoietic growth factors. But also “classical” hormones, such as thyroid or adrenal hormones, have significant influence on blood cell production. More detailed information about stem cell biology and their regulation can be obtained in [2], [3]. Much can be learned also from the pathophysiology of bone marrow failure in acquired aplastic anemia [4]. However, in face of the rapidly increasing knowledge with ongoing discovery of novel factors and interactions, it is impossible at present to provide a definite and comprehensive description of the regulation of hematopoiesis. A provisional, simplified overview is given in Figure 2, a selection of cytokins is listed in Table 2. A panel of mature blood cells is displayed in Figure 6 A – F.

Table 2. List of selected cytokins

Factor	Major source(s)	Main effect(s)
Granulocyte-colony stimulating factor (G-CSF)	monocytes, fibroblasts	stimulation of generation and differentiation of neutrophils
Granulocyte- macrophage-colony stimulating factor (GM-CSF)	T-cells, fibroblasts, endothelium	stimulation and differentiation of progenitor cells for granulocytes, monocytes, platelets, erythrocytes
Erythropoietin	kidney	stimulation of erythropoesis, some effect also on platelet production
Thrombopoietin	liver	stimulation of platelet production
Interleukin-1 (IL-1)	monocytes	enhancement of other growth factors, and of immune reactions
IL-2	T-cells (helper cells)	activation and proliferation of T-cells
IL-3 (multi-CSF)	T-cells	proliferation (self-renewal) and

		differentiation of early progenitor cells
IL-4	T-cells, macrophages	stimulation of B-cells
IL-6	macrophages, fibroblasts, T-cells	differentiation of B- and T-cells, acute-phase reaction (enhanced synthesis of fibrinogen and other proteins)
IL-16	T-cells	chemotaxis of CD4-cells, inhibits proliferation of HIV in infected cells
Stem cell factor (SCF)	fibroblasts and other cells	stimulates CD34-positive stem cells
Tumor necrosis factor (TNF	macrophages	enhancement of inflammatory reactions, pro-coagulatory stimulation of endothelium, antitumor effects
Interferons (α, β, γ)	leukocytes, fibroblasts, T-cells	various antiviral, antiproliferative (some types of malignancy) and immune-modulating effects
Platelet-derived growth factor (PDGF)	megakaryocytes and platelets	growth stimulation of vessel wall and inflammatory cells

A) Band form; B) Segmented neutrophil; C) Eosinophil; D) Basophil; E) Monocyte; F) Lymphocyte

Compare size with surrounding erythrocytes and platelets.

2.1.2. *Red Cells, Hemoglobin*

The red cells, the erythrocytes, are produced by proliferation and differentiation of precursor cells (erythroblasts) in the bone marrow. The mature erythrocytes do not contain a nucleus and are no more capable of cell division. In the young erythrocytes, during the first days after they left the bone marrow, some residues of RNA and organelles can be found by a special stain. These cells are called reticulocytes. The normal life span of erythrocytes is about 110 d, thereafter they are phagocytized and degraded in macrophages of the spleen and the so called reticulo-endothelial system (RES). The iron and the protein of the erythrocytes is recycled for biosynthesis, the heme is degraded and metabolized into bilirubin, which is transported by the blood stream into the liver, where metabolites are excreted in the bile.

Mature erythrocytes have a characteristic shape of a biconcave disk. Normal red cells have a diameter of 7.5 to 8.7 µm; variations may be a diagnostic feature of disease states, e.g., smaller erythrocytes occur in iron deficiency, or larger cells in vitamin B_{12} deficiency. Erythrocytes have an average volume of 90 fL, and their shape provides a particularly large surface area of about 136 μm^2, which is important for their function in gas exchange. Red cells show a pronounced deformability which is needed for their passage through narrow capillaries. The erythrocytes are susceptible to alterations of the osmotic pressure and will shrink in hypertonic and swell in hypotonic solution until they are lysed at a critically low osmolality. Although the red cells do not contain a nucleus, they are quite differentiated cells which possess also an energy metabolism. Glucose is utilized as a source of energy via the glycolytic pathway and the hexose monophosphate shunt; red cells lack, however, the citric acid cycle. The energy is needed (1) to maintain the iron of hemoglobin in the divalent form; (2) to maintain the electrolyte gradient with high potassium level inside the erythrocytes, (3) to protect hemoglobin and enzymes from oxidation, and (4) to retain the biconcave shape of the cell.

The characteristic function of red blood cells, the transport of oxygen, is carried out by hemoglobin. Hemoglobin is a complex of a tetrameric protein (globin) component and the heme (which is made up by a characteristic porphyrin ring system similar to that found in chlorophyll, and divalent iron). The globin component consists of two alpha chains and two other chains. In adults, most of the hemoglobin contains beta chains (giving a formula $\alpha_2 \beta_2$). This hemoglobin is named hemoglobin A. This nomenclature must not be mixed up with the AB0 blood group system. In the fetal period, and in some hereditary disorders of hemoglobin metabolism, hemoglobin contains other molecules instead of the beta chains, e.g., gamma chains in the fetal hemoglobin ($\alpha_2 \gamma_2$, hemoglobin F). The binding of oxygen to hemoglobin is influenced by the temperature, pH value, and the red cell content of 2,3-diphosphoglycerate. The oxygen dissociation curve shows a typical S-shape.

2.1.3. *Leukocytes, Cytokins*

All cells circulating in the blood, which are neither erythrocytes nor thrombocytes, are summarized by the expression “leukocytes” or “white blood cells”. The leukocytes in the blood can be divided into granulocytes, monocytes, and lymphocytes.

Granulocytes. The name “granulocytes” refers to the characteristic granules making up the specific appearance of these blood cells under the light microscope. The granulocytes can be differentiated by the standard panoptic staining of blood smears (e.g., Pappenheim or Wright) as neutrophil, eosinophil, or basophil granulocytes.

Neutrophil granulocytes normally comprise more than 50 % of the total leukocyte count. They are derived from precursor

cells in the bone marrow (myeloblasts and myelocytes). During the proliferation and increasing differentiation of these precursor cells, the granules undergo a maturation process, and the nucleus changes from the big and round shape in myeloblasts to the beanlike appearance of the so called “band forms” of the young granulocytes. During their further live span, the nucleus of the neutrophil granulocytes undergoes progressive segmentation. While an increase of band forms in the blood smear is a sign of an acute challenge, in most cases bacterial infection, the appearance of granulocytes with an abnormally high number of segments may point to certain hematological diseases with impaired blood cell production. Normally, the neutrophil granulocytes circulate only several hours in the blood circulation, before they extravasate and enter the tissues. They are very reactive, nonspecific phagocytes, which can be viewed as the first line of combat against any invasion of pathogenic or toxic agents. The neutrophil granulocytes play a significant role in the surveillance against bacteria and fungi at outer surfaces of the body, e.g., the oral cavity. Therefore, a lack of functional granulocytes (e.g., in an acute leukemia or bone marrow failure) may lead to characteristic, severe local infection in the mouth (gingiva, tonsils) or in the perianal area. In individuals with normal bone marrow function, the production of neutrophil granulocytes can be increased over a wide range in case of an acute challenge such as an acute bacterial infection, intoxication or major trauma, with an increase of the total white cell count and the proportion of band forms in the blood. This increase is initiated by cytokins, particularly IL-3, GM-CSF and G-CSF; IL-8 is a strong activator of neutrophil granulocytes. The neutrophil granulocytes are activated by a variety of nonsoluble (e.g., pathogenic microorganisms) or soluble (endotoxins, leukotrienes, complement factors, fibrinopeptides) stimuli. They are capable of active locomotion, and they are attracted to the site of the lesion by chemotaxis. The phagocytosis is strongly enhanced by the so-called opsonization of particles, which means their coating by molecules such as complement factors or immunoglobulins. The neutrophil granulocytes possess a very efficient apparatus for intracellular killing of ingested microorganisms and degradation of foreign protein. They have the capacity to produce highly reactive oxygen radicals by means of specific enzymes, such as myeloperoxidase, in their azurophilic granules. The specific granules contain several enzymes such as acid hydrolases, alkaline phosphatases, and proteolytic enzymes, particularly elastase, with a high capacity to degrade foreign materials. During activation and phagocytosis, oxygen radicals and enzymes may leak out into the surrounding, where they may damage structures and proteins. Proteases from neutrophil granulocytes, particularly elastase, are thought to contribute to extravascular fibrinolysis [5].

Eosinophil Granulocytes. The eosinophil granulocytes contain specific granules which are larger than those of neutrophils and are stained red by eosin. Normally, they comprise 2 – 4 % of the total leukocyte count. The nucleus usually has two segments. Besides enzymes like in neutrophil granulocytes, the specific granules contain a so-called “major basic protein”, which makes up about 50 % of the granule content and plays a role in the killing of parasites and mammalian tissue cells. Besides their ability to nonspecific phagocytosis, eosinophil granulocytes exhibit some characteristic features: The cytotoxic destruction of parasites in cooperation with macrophages, cytotoxic damage to tissue cells (e.g., cells of the respiratory tract in patients with asthma bronchiale), and neutralization of mediators from mast cells such as histamine, serotonin, and bradykinin. During anaphylactic reactions, eosinophils contribute to the attenuation of the inflammatory process. Production and function of eosinophils is controlled by cytokins (e.g., IL-5), and is also influenced by steroid hormones (decreased by corticosteroids, increased by estrogens and androgens).

Basophil granulocytes have a very characteristic appearance due to their large and dark blue granules, which often hide the nucleus. The granules contain high amounts of heparin and biogenic amines (histamine, serotonin) and bradykinin. The effect of these mediators is generally an enhancement of inflammatory reactions by vasodilatation and prevention of coagulation in order to maintain free access for inflammatory cells and mediators to the area of the lesion. Basophils possess receptors for immunoglobulin E (IgE) on their surface and are specifically involved in type I allergic (anaphylactic) reactions, where they cause severe hypotension or even lethal shock by massive release of histamine and bradykinin.

Monocytes belong to the group of large, phagocytizing cells which are called macrophages. They share a common progenitor cell with the granulocytes in the bone marrow. The macrophages circulating in the blood stream are called monocytes due to their round, oval or kidney-shaped nucleus, which is not segmented in contrast to granulocytes. After a circulation time of a few days in the blood, the monocytes move to the tissues, where they may stay alive for months. The macrophages in the tissues are called histiocytes, or in the liver also Kupffer cells. Macrophages may be found in all tissues of the organism, but particularly rich of these cells are the liver, the spleen, lymphnodes, and bone marrow, as well as areas of chronic inflammation, particularly granulomas. Macrophages are able to kill bacteria and to phagocytize necrotic material, e.g., in tissue repair after a local infection has been overcome. Besides that macrophages have a very important function in the specific immune defense due to their cooperation with lymphocytes. After phagocytosis and proteolytic digestion, fragments of foreign material are transferred to the macrophage surface, where they are “presented” to lymphocytes.

Lymphocytes are produced in the bone marrow and in lymphatic organs such as the spleen, lymphnodes, tonsils, appendix, Peyer's plaques, and — during childhood — the thymus. Lymphocytes in the peripheral blood can be identified as small to mid-sized cells with a round nucleus and few cytoplasm. In contrast to other blood cells, the maturity stage and the specific function of the lymphocytes cannot be differentiated by morphologic examination. In order to identify and quantitate the different functional subsets of lymphocytes, the staining of characteristic antigens on the cell surface by specific antibodies has been introduced. The antigens have been described in the “cluster of differentiation” (CD-) nomenclature, leading to a large and still expanding list of antigens on blood and bone marrow cells (Table 3). The determination of the CD-antigens in cell samples is nowadays a very important tool for the differential diagnoses of disorders of the hematopoietic and immune system. A well known example is the disturbed balance between CD-4 and CD-8 lymphocytes in acquired immune deficiency syndrome (AIDS). The CD-antigens resemble in many cases important functional receptors on the cell surface.

Table 3. Cluster of differentiation (CD)-nomenclature; examples of CD entities and their expression by blood cells

CD designation	Remark	Main cell reactivity
CD3	T-cell receptor complex	T-cells
CD4	MHC class II and HIV receptor	T-cells
CD8	MHC class I receptor	T-cells

CD14	lipopolysaccharide (LPS) receptor	macrophages, granulocytes, dendritic cells
CD19	surface Ig family	B-cells
CD34	used for stem cell selection	hematopoietic stem cells
CD41	GP IIb-IIIa (fibrinogen receptor)	platelets
CD62P	P-selectin	activated platelets and endothelial cells

Lymphocytes can be divided into two main groups, the *T-lymphocytes* (which are primed in the thymus), and the *B-lymphocytes* (which are primed in the bone marrow, the equivalent to a specific organ of birds, called *Bursa Fabricii*).

T-Lymphocytes. The group of T-lymphocytes includes cells with important regulatory function (so called helper or suppressor cells), as well as cytotoxic cells. T-helper or inducer cells (T_H) can be divided into subpopulations: T_{h1}*cells* support the proliferation and the function of T-lymphocytes and thus the cell mediated immunity, T_{h2}*cells* support the differentiation of B-lymphocytes to the antibody producing plasma cells. There is evidence that T-suppressor cells are probably not a defined T-cell subpopulation of its own, “suppression” of the immune answer appears to be rather a special functional state of cytotoxic or helper cells. For instance, T_{h1}cells promote their own development, but inhibit at the same time the development of T_{h2}cells and vice versa.

A specific immune reaction is initiated by close contact and cooperation of an antigen-presenting cell (macrophages or dendritic cells) and T-cells. The interaction proceeds on several levels. A nonspecific cell adhesion is mediated by adhesion molecules, a specific interaction is brought about by molecules of the so-called major histocompatibility complex (MHC) which can be divided into class I and class II molecules. The pattern of MHC-antigens of an individual is the basis for the human leukocyte antigen (HLA) typing, which is useful for the assessment of compatibility in organ transplantation, as well as in platelet transfusion. The MHC-proteins are important for the antigen presentation. MHC-molecules bind short peptides derived from degraded antigens, class I peptides of viral proteins or endogenous (tissue derived) antigens, and class II those of exogenous, e.g., bacterial proteins. The MHC-molecules bearing the antigen peptides react with a T-cell receptor which recognizes specifically the presented antigen. By this way, T-cells with antigen specific T-cell receptors are activated and produce and release cytokins. Particularly by IL-1 and IL-2, the immune reaction is initiated and enhanced, and the antigen specific T-cell clones can proliferate and expand.

A subpopulation of T-cells possesses direct cytotoxic activity. These cells are able to attack specifically target cells presenting the antigen by direct cell contact and a complex reaction involving the release of proteins which induce a perforation of the membrane (perforine) and enzymes (granzyme A – H).

There are also *effector cells* which cannot be allocated to the T- or B-cell groups and are called natural killer cells.

B-Lymphocytes. The humoral immunity is a function of B-lymphocytes. They are stimulated by cytokins released from T $_{h2}$cells in cooperation with the antigen-presenting cells. On the surface of B-cells, their specific immunoglobulin is exposed in a way similar to a receptor. If the antigen, e.g., a virus protein on cell surface, is presented in a coordinated and repetitive arrangement, the B-cells may be activated directly without T-cell help [6].

A common principle of T- and B-cells is that a huge repertoire of preformed cells exists, each of which reacts specifically via its T-cell receptor or surface immunoglobulin to a certain antigen. If the body is confronted with such an antigen, there will be a clonal expansion of the lymphocytes which are able to react specifically with this antigen, and this expansion leads to a strong cytotoxic or antibody-mediated immune reaction.

2.1.4. *Thrombocytes*

Thrombocytes, also called blood platelets, are the smallest blood cells. They contain no nucleus, but several specialized organelles. Thrombocytes are derived from megakaryocytes in the bone marrow. In contrast to the other blood precursor cells megakaryocytes do not undergo cell divisions, but endomitosis leading to a polyploid huge cell nucleus, surrounded by a growing cytoplasm, which is roughly “granulated” at the end of maturation. The big “granules” are the preformed platelets, which develop by progressive spreading of a membrane system throughout the megakaryocyte cytoplasm and thus demarcation of the future platelets, and simultaneously development of the organelles. The maturation takes a few days, and one megakaryocyte can produce up to about 2000 platelets. At the end of maturation, the platelets fall apart from their mother cell and enter the blood stream, leaving the nude nucleus.

Thrombocytes have a life span of about one week in the circulation, where they are “a patrol”, the task of which is to detect any disturbances of the integrity of blood vessels and to seal them rapidly in order to prevent excessive blood losses. Due to this function the thrombocytes are the first line of hemostasis. Therefore, the time between a standardized cut into the skin and the termination of bleeding (“bleeding time”) is mainly a function of the thrombocytes. As long as the thrombocytes circulate through vessels with an intact endothelium, they are in a resting state; it has been calculated, that a platelet may pass more than 8000 times through the whole circulation during his life span without being activated. Aged platelets are cleared by the reticulo-endothelial system, mainly in the spleen. The spleen is also a kind of a storage pool which may host about a quarter to a third of the total platelet mass and may release them into the circulation by contraction in case of a challenge like a major injury. Spleenectomized individuals tend to have higher platelet counts in their blood.

Platelets have a discoid shape in the resting state and do not contain a nucleus. They possess characteristic and specific organelles: The α-granules contain proteins, mainly platelet factor 4 and β-thromboglobulin — which are anti-heparin factors — fibrinogen and coagulation factors, as well as thrombospondin, plasminogen activator inhibitor (PAI), and the platelet derived growth factor (PDGF). A very characteristic type of granules are the dense bodies, which contain serotonin

and adenosine diphosphate (ADP). The so-called dense tubular system is involved in the production of prostanoids. The open canalicular system is a system of channels spreading throughout the cell, enabling a rapid transport of the constituents to the outside of the cell, which is important for the release reaction upon activation of the thrombocytes. The outer plasma membrane of thrombocytes contains in the resting state only few negatively charged phospholipids, but a high concentration of the negatively charged phosphatidyl serine is located at the inner layer of the cell membrane. Of functional importance are also the cytoskeleton and in particular contractile proteins (actinin and myosin) which are important for the shape change (see below), and the clot retraction.

The thrombocytes are very reactive cells and are rapidly activated, whenever they come into contact with other surfaces than the intact endothelial cells. The are activated, in particular, by subendothelial structures such as collagen fibers or foreign surfaces such as glass. In contrast to granulocytes, thrombocytes do not have the capacity of locomotion. They are passively driven by the blood stream to the site of lesion. It has been estimated, that during the normal bleeding time of about five minutes about 10^{12} platelets may pass the defect of the vessel wall, but only about 10^5 are found in the clot. The platelets are particularly reactive in areas of fast and turbulent blood flow, where a considerable shear stress is imposed to them. This is one of the reasons, why thrombocytes play a much more prominent role in arterial than in venous vessels. The activation of thrombocytes leads to a rapid, microscopically visible reaction, the so-called shape change: The cell body changes from a discoid to a spherical shape, and a number of pseudopods is extruded. The electrical charge of the outer membrane changes by a fast transfer of phosphatidyl serine from the inner to the outer surface, and the platelets become “sticky”. The electrical charge is also of great significance for the procoagulant function of platelets, since the activated platelet membrane is a template for complexes of activated coagulation factors (see below). Besides the shape change, the thrombocytes undergo also the so-called release reaction, which means the rapid extrusion of mediators, which are important for the activation of surrounding thrombocytes and for other processes, such as the initiation of blood coagulation, and promotion of cell growth in the injured vessel wall by PDGF. In the activation of platelets, presently three pathways can be differentiated. The first pathway is mainly triggered by platelet adhesion to, e.g., collagen fibers, and involves the formation of prostanoids. By the action of a phospholipase, arachidonic acid is liberated from the platelet membrane and subsequently metabolized to prostanoids. An important step is the generation of cyclic peroxides by the enzyme cyclooxygenase, which is a target for the antiplatelet effect of aspirin. The cyclic peroxides are further metabolized to thromboxane A_2, which is one of the most potent mediators of platelet activation and vasoconstriction (see also ⟶ Cardiovascular Drugs; ⟶ Prostaglandins). In endothelial cells, there is also a cyclooxygenase pathway, which generates a counterpart to thromboxane A_2, prostacyclin, which is a potent inhibitor of platelet activation and a vasodilator (⟶ Prostaglandins). The second pathway of thrombocyte activation is mediated by ADP, which is stored in high amounts in the dense body granules of the platelet. ADP acts via a specific P_2T purine receptor. The ADP-pathway is also stimulated by thromboxane A_2, serotonin, and adrenaline (epinephrine). ADP may be liberated from platelets also in a turbulent blood stream with high shear stress leading to cell damage. The third pathway of platelet activation is mediated by thrombin, the key enzyme of blood coagulation (see below). Besides the three pathways outlined above, there are additional agonists and antagonists, such as platelet activating factor or nitric oxide. Generally, after activation by a primary agonist, the other pathways lead to a strong enhancement of the activation in a sense of a positive feed back reaction. The intracellular events associated with activation by the above agonists, include an increase of the intracellular calcium concentration, the formation of diacylglycerol and inositol triphosphate, leading to an activation of proteinkinase C, and an increase of cyclic AMP. An overshooting reaction should be prevented by natural antagonists, such as prostacyclin or nitric oxide.

The thrombocyte surface possesses a number of functionally important receptors, which have been mentioned above: A purine receptor, a thromboxane A_2 receptor, a thrombin receptor, an α_2-adrenergic receptor, and a platelet activating factor receptor. Besides that, there are a number of functionally important glycoproteins (GP), which act as receptors for specific structures. Important examples are (1) the GP IIb-IIIa, a receptor for fibrinogen, von Willebrand factor (vWF, a multimeric protein composed of up to 40 subunits each having an apparent molecular mass of 500 000), fibronectin, and vitronectin, which is important for platelet aggregation; (2) GP Ib-IX, a receptor for von Willebrand factor, which is important for platelet adhesion; and (3) GP Ia-IIa, a receptor for collagen. Platelet adhesion means the adherence of thrombocytes to subendothelium or foreign surfaces, which involves adhesive proteins and particularly von Willebrand factor. Adhesion has to be differentiated from aggregation, which means sticking of platelets to each other in the blood stream. Aggregation is effectively inhibited by aspirin, blocking the thromboxane A_2 pathway, while aspirin does not substantially influence adhesion. During aggregation, fibrinogen forms “bridges” between GP IIb-IIIa of aggregating platelets.

2.2. Plasma Proteins

2.2.1. *Analysis of Plasma*

Plasma, the cell-free part of blood, contains numerous different proteins, each having certain and essential function(s). Depending on the desired aim plasma proteins may be separated by different means. Generally, a distinction is made between analytical and preparative purposes. These purposes dictate which technique to apply. For analyzation of plasma electrophoretic techniques are preferred because they are both easy to perform and of remarkable resolving power. In this case plasma is subjected to an electric field whereby the proteins are separated into different groups. The resolution depends upon the electrophoretic technique applied. Using very common but relatively poor resolving techniques (e.g., zone electrophoresis) plasma is separated into six major fractions, constituting the most prominent proteins: Albumin, α_1-, α_2-, β-, γ-globulins, and fibrinogen (Fig. 7). With more elaborated separation (and detection) techniques (see below), however, plasma proteins can be separated into much more distinct fractions, hence allowing also the detection of minor constituents (examples are given in Table 4): From Table 4 it becomes obvious that plasma proteins may be classified according to several criteria, among others normal concentration, size, electrophoretic mobility, function.

Figure 7. Electrophoretic analysis of normal plasma. Typical separation of plasma proteins by electrophoresis

The anode is to the left. After electrophoresis the protein bands are stained and subsequently scanned by densitometry.

Table 4. Plasma proteins

Protein	Plasma concentration, mg/mL	Biological function	M_r
Albumin	40 – 50	transport, colloidosmotic	67 000
IgG Globulin	8 – 18	antibody	155 000
Fibrinogen	2 – 4.5	coagulation	340 000
Transferrin	2 – 4	iron transport	76 000
α_1-Proteinase inhibitor	2 – 3.5	inhibitor of serin proteases	54 000
α_2-Macroglobulin	1.5 – 3.5	general inhibitor of proteases	725 000
α_1-Lipoprotein	1.7 – 3	lipid, hormone transport	28 000
IgA Globulin	0.9 – 4.5	antibody	160 000
IgM Globulin	0.6 – 2.5	antibody	975 000
Haptoglobin 1-1, 2-1, 2-2	0.9 – 3	hemoglobin binding,	86 000
β-Lipoprotein	0.6 – 1.5	lipid, hormone transport	27 000
Hemopexin	0.5 – 1.1	hemin binding	57 000
C3-Component	0.5 – 1.2	complement factor	185 000
α_2-HS Glycoprotein	0.4 – 0.85	opsonin	49 000
Inter- α-trypsin inhibitor	0.4 – 0.7	trypsin inhibitor	160 000
α_1-Antichymotrypsin	0.3 – 0.6	chymotrypsin inhibitor	68 000
Ceruloplasmin	0.15 – 0.6	oxidase	132 000
Gc-Globulin	0.2 – 0.55	vitamin D3 binding	51 000
C1-Inhibitor	0.15 – 0.35	protease inhibitor	104 000
β_2-Glycoprotein I	0.15 – 0.3	heparin binding	40 000
C4 Component	0.2 – 0.5	complement factor	206 000
Prealbumin	0.1 – 0.4	thyroxin, retinol binding	55 000
Antithrombin III	0.15 – 0.2	inhibitor of activated coagulation factors	60 000
C3-Proactivator	0.1 – 0.4	proteinase	90 000
C1q-Component	0.1 – 0.25	complement factor	400 000
C1r-component	0.1	complement factor	83 000
C9-Component	0.08	complement factor	71 000
C8-Component	0.08	complement factor	153 000
C6-Component	0.075	complement factor	105 000
C7-Component	0.055	complement factor	92 000
Plasminogen	0.06 – 0.25	zymogen of plasmin	91 000
β_2-Glycoprotein III	0.05 – 0.15	unknown	35 000
Prothrombin	0.05 – 0.12	zymogen of thrombin	72 000
C5-Component	0.04 – 0.15	complement factor	180 000
9.5S α_1-Glycoprotein	0.04 – 0.08	constituent of amyloid deposits	308 000
Retinol binding protein	0.03 – 0.06	transport of retinol (vitamin A)	21 000
8S α_3-Glycoprotein	0.03 – 0.05	unknown	220 000
Transcortin	0.04	cortisol transport	56 000
C1s-Component	0.02 – 0.04	complement factor, esterase	85 000
Factor XIII	0.01 – 0.04	fibrin cross-linking, transglutaminase	340 000
Properdin	0.01 – 0.03	complement regulator	184 000
C2-Component	0.01 – 0.03	complement factor	110 000

Thyroxin binding glycoprotein	0.01 – 0.02	binding of thyroxin,	54 000
Factor X	0.01	zymogen of FXa	62 000
Zn α_2-Glycoprotein	0.02 – 0.15	unknown	41 000
Lysozyme	0.007 – 0.02	bacteriolysis	14 500
Serum cholinesterase	0.005 – 0.015	cleavage of cholin esters	348 000
Factor V	0.005	coagulation cofactor	330 000
Factor IX	0.004	zymogen of FIXa	62 000
Protein C	0.004	zymogen of inhibitor of coagulation	62 000
IgD Globulin	0.003 – 0.1	antibody	175 000
IgE Globulin	0.001 – 0.0014	antibody	190 000
Factor VII	0.0005	zymogen of FVIIa	50 000
Factor VIII	0.00015	coagulation cofactor	280 000

The *size* of a given protein is determined by the number of amino acids it is composed of and by posttranslational modifications. Most plasma proteins are modified by attachment of nonprotein side chains to the molecules (typical examples are sugar residues and phospholipids).

The *electrophoretic mobility* is determined by the relative amounts of positively, negatively, or uncharged amino acids, as well as by structure and size, depending upon which individual separation technique is applied (native gel electrophoresis, denaturing gel electrophoresis under reducing and nonreducing conditions, respectively, and isoelectric focusing, the latter being the system with the highest resolving power). Also, combinations are possible, e.g., isoelectric focusing followed by denaturing SDS gel electrophoresis.

The numerous proteins of plasma execute manifold functions. Some prominent examples are immunoglobulins as antidotes against foreign molecules, albumin for transport function, coagulation factors for sealing lesions, cytokins for the exchange of information between cells, numerous inhibitors for, e.g., the control of enzymatic reactions against overshooting.

To characterize single protein components of plasma these must normally be isolated from the other plasma constituents. For this purpose they are subjected to a series of separation techniques, each taking advantage of a different characteristic of the protein in question. Typical examples for fractionation sequences are salt (or alcohol) precipitation, hydrophobic interaction chromatography, ion exchange chromatography, affinity chromatography (if available), gel filtration, in certain cases reversed-phase chromatography.

2.2.2. *Coagulation Factors*

As mentioned above, coagulation factors have evolved as a response of organisms against injuries. It is now generally accepted that the system of coagulation may be divided into two branches, the extrinsic system and the intrinsic one (see Fig. 8). The extrinsic branch represents the immediate and direct response to lesions of the organism. This part of the coagulation system is composed of factor VII/VIIa and tissue factor, two coagulation components which come into contact with each other only in the case of disturbances of the normal tissue organization. The intrinsic branch (represented by factors XII, XI, and IX) may be interpreted as an additional amplification mechanism which is turned on, once the extrinsic system has become activated. As shown in Figure 8, both branches are interconnected at the level of coagulation factor X. Downstream of factor X both systems ultimately lead to the formation of fibrin by thrombin. From Figure 8 it can also be derived that normal coagulation is restricted to the vessel walls due to the dependence of the necessary events upon phospholipids. As the complete system is composed of a cascade of protease zymogens (i.e., enzyme precursors), this system is prone to overshooting and must be under tight and rapid control. This is fulfilled by specific and efficient inhibitors, such as antithrombin (AT) and tissue factor pathway inhibitor (TFPI). In addition, thrombin is transformed from a procoagulant protein into an anticoagulant protein by interaction with thrombomodulin.

Figure 8. Scheme of blood coagulation

The events of the clotting cascade are illustrated schematically here. Only the unactivated coagulation factors are presented with the exception of factor IIa (thrombin) for simplicity. The organism's immediate response to a tissue lesion is shown on the left (FVII/TF to thrombin). The contact activation pathway (via FXII to FIX) is also illustrated. The whole process is dependent upon phospholipids which are contained in the cellular components of the system (vessel wall and platelets).

TF = Tissue factor; HMWK = High molecular weight kininogen: Pk = prekallikrein

Coagulation factors are listed according to their historical order of discovery by giving the term coagulation factor (often shortened to factor) followed by roman numbers. Most of the coagulation factors must be altered before they can fulfill their physiological function. These proteolytically modified coagulation factors are labeled by adding the letter “a” for activated.

Coagulation Factor I (Fibrinogen). Fibrinogen [9001-32-5], M_r 340 000, is the most prominent coagulation factor in plasma (3 mg/mL). Fibrinogen is the precursor of fibrin [9001-31-4], which is generated as the final event of clot formation. During normal coagulation fibrinogen is converted to fibrin by thrombin. Other enzymes of nonplasma origin, however, can induce clotting as well, e.g., papain and several proteolytic components of certain snake venoms. Several microorganisms, such as *Staphylococcus* also can cause coagulation by cleaving fibrinogen.

Fibrin, the cleavage product of fibrinogen is poorly soluble in aqueous salt solutions. This low solubility is, in the course of coagulation, further reduced by activated factor XIII (see below) to allow clot stabilization.

Coagulation Factor II (Prothrombin). Prothrombin [9001-26-7], M_r 72 000, is contained in normal plasma at a concentration of 100 µg/mL. It is a glycosylated protein containing about 5 % carbohydrate. Like several other coagulation factors it is produced in the parenchymal cells of the liver. For normal prothrombin synthesis vitamin K is required, as is for the synthesis of other zymogens of the coagulation pathways. During activation to the serine protease thrombin the protein's molecular mass is nearly halved to 37 000 whereas the other coagulation factors (see below) are shortened by few amino acids only when activated (the leaving peptide termed activation peptide). Although thrombin is the final protease of the coagulation cascade it plays an important role in regulating its own activity and production. This is accomplished by both, feedforward activity in activating cofactors V and VIII and negative feedback activity by activating inhibitors of coagulation including its own (protein C and protein S). Thus, thrombin is not only a procoagulant but simultaneously an important regulator of normal hemostasis. A rather common genetic variation in the prothrombin gene (G to A transition) at position 20210 leads to elevated prothrombin levels in plasma and is considered to increase the risk for venous thrombosis in people affected.

Coagulation Factor III (Thromboplastin, Tissue factor). Thromboplastin [9035-58-9] was initially discovered as a poorly defined substance that in coagulation experiments ultimately led to thrombin formation. It was then found to be composed of one part protein noncovalently bound to one part of heterogeneous phosphatides. The protein component is tissue factor (M_r 47 000), a glycoprotein with Ca^{2+}- dependent affinity to factors VII and VIIa. Unlike the other coagulation cofactors it does not circulate in the blood but is integrated into cellular membranes not normally in contact with the blood stream. A tissue injury results in exposure of tissue factor to blood, thus enabling its contact with FVII/ FVIIa. It is assumed to stabilize factor VIIa in a proteolytically active conformation to catalyze the conversion of FIX and FX to FIXa and FXa, respectively. The designation factor III meanwhile has been replaced by listing the respective components individually, namely tissue factor, phospholipids.

Coagulation Factor IV (Calcium). Calcium ions are required for most individual steps of coagulation as catalyst. The cation acts as a bridge between phospholipids in cellular membranes and carboxy glutamyl residues in certain coagulation factors. This results in a conformational change in the respective coagulation factor leading to formation of a complex which can be activated by the protease produced in the previous step of the coagulation cascade. Similar to the situation with FIII, calcium is the currently used denomination.

Coagulation Factor V (Plasma Accelerator Globulin). Factor V, M_r 350 000, is the inactive precursor to factor Va (see factor VI, below). Like factor VIII (see below) it is not a zymogen. Its concentration in plasma is about 10 µg/mL. After activation of factor V by thrombin, the resulting factor Va serves as a cofactor for the activation of prothrombin to thrombin by activated factor X, thus facilitating feed forward amplification of the clotting process. A genetically determined defect termed “factor Va Leiden” (Arg 506 is exchanged for Gln) results in activated protein C (APC) resistance, thus leading to an increased risk for thromboembolic complications. This genetic defect is almost exclusively restricted to humans of the western hemisphere. In this population, however, this defect is quite evident (one out of ten people is affected by this mutation).

Coagulation Factor VI (Activated Factor V). Unlike all other terms for coagulation factors, factor VI is the designation for (just) the activation product of another clotting factor (FV, see above), therefore it is somewhat confusing and its use is discontinued.

Coagulation Factor VII (Proconvertin). Proconvertin [9001-25-6], M_r 50 000, is the least prominent vitamin K dependent coagulation factor with a plasma concentration of 0.5 µg/mL. Together with tissue factor and phospholipids, activated factor VII (FVIIa) forms the initiator of coagulation as a response to tissue damage by activating factor X (extrinsic coagulation pathway) and by activating factor IX (intrinsic pathway). In contrast to the other coagulation factors some (about one in thousand molecules) activated factor VII is reported to circulate in the blood.

Coagulation Factor VIII (Antihemophilic Globulin A). Factor VIII [9001-27-8], M_r 280 000, circulates in plasma in tight association with von Willebrand factor. Due to its tight association with vWF the molecular mass of FVIII has long been overestimated. The physiological function of this tight association is assumed to lie in transport and protection of FVIII. In addition, vWF mediates the association of FVIII with platelets (see Section Thrombocytes). The normal plasma concentration of FVIII is 150 ng/mL, classifying it as a trace protein. Hereditary defects in FVIII synthesis are the cause for hemophilia A, leading to severe bleeding disorders. After activation by thrombin (or FXa), FVIIIa serves as a cofactor for the activation of FX by FIXa at a cellular phospholipid surface.

Coagulation Factor IX (Christmas Factor, Antihemophilic Factor B). Like the other factors of the prothrombin complex (FII, FVII, FX, and protein C and protein S) factor IX [9001-28-9], M_r 62 000, is a glycoprotein. It also contains several γ-carboxy glutamic acid residues that are essential for its function. FIX has a plasma concentration of 4 µg/mL. Similar to the situation with FVIII, genetically determined deficiency in this coagulation factor results in a bleeding disorder and a prolonged partial thromboplastin time, called hemophilia B in this case. Factor IX is the final zymogen of the intrinsic coagulation pathway. Once activated, the resulting enzyme together with activated FVIII, phospholipids, and calcium forms the tenase complex, that activates factor X.

Coagulation Factor X (Stuart Prower Factor). Factor X [9001-29-0] is the link between the intrinsic coagulation pathway and the extrinsic one, the former pathway being considered as an amplification mechanism of the latter. After activation by either FIXa (intrinsic) or FVIIa (extrinsic) to FXa this enzyme, with FVa as cofactor, phosholipids, and calcium ions forms the prothrombinase complex that converts prothrombin to thrombin. It can be interpreted as a feed forward amplification that activated factor X together with tissue factor can activate FVII, thus enabling the activation of additional FIX and FX molecules. Factor X has an apparent M_r of 67 000 and is contained in normal plasma at a concentration of 10 µg/mL. Unlike the other procoagulants of the prothrombin complex nonactivated FX is composed of two peptide chains held together by a

disulfide bridge.

Coagulation factor XI [9013-55-2], M_r 160 000, is a zymogen involved in the intrinsic coagulation pathway resulting by contact with foreign material (contact activation). It is composed of two identical peptide chains held together by a disulfide bond. After activation by factor XIIa (see below) it will activate FIX. The plasma concentration of FXI is 5 µg/mL.

Coagulation factor XII (Hagemann Factor), [9001-30-3], M_r 90 000, is the first zymogen in the contact activation of the coagulation system and the only one which is not dependent upon the presence of calcium ions for function. Its normal plasma concentration is 40 µg/mL. No bleeding disorders are reported as a consequence of a deficiency in this factor, people affected rather carry an increased risk for thromboembolic disorders. FXII plays an important (although not fully understood) role not only in the coagulation system but also due to its link to the kallikrein and plasmin systems.

Coagulation Factor XIII (Fibrin Stabilizing Factor). Unlike the aforementioned zymogens factor XIII [9013-56-3] is not the precursor of a protease, but of a transglutaminase. Once activated by thrombin, the enzyme stabilizes the fibrin clots by introducing covalent links between lysine and glutamine residues in individual fibrin molecules thus rendering the clot insoluble. It also introduces covalent links between other plasma proteins, e.g., fibrin, vitronectin, and α 2-plasmin inhibitor. Plasma FXIII is a heterodimer ($FXIIIA_2B_2$) composed of two subunits each, called FXIII-A (the proenzyme) and FXIII-B (formerly called FXIII-S). Activation of FXIII to FXIIIa is accomplished by splitting of an activation peptide from the A-chains. The plasma concentration of FXIII (M_r 320 000) is 20 µg/mL.

Protein C, M_r 62 000, is the zymogen of an inhibitor of coagulation. Like FX it is a two-chain molecule. Its plasma concentration is 5 µg/mL. After activation by thrombin bound to thrombomodulin (a “receptor”-like protein on the surface of endothelial cells), protein C together with its cofactor (activated protein S, see below) will inactivate activated factors V and VIII, respectively. Thus it acts as a modulator of coagulation by interference with FXa generation as well as thrombin formation. Due to its charge characteristics protein C is found in the prothrombin complex (factors II, VII, IX, X) during plasma fractionation. Genetically determined deficiency in protein C results in elevated risk for thromboembolic complications.

Protein S, M_r 69 000, has a plasma concentration of 10 µg/mL. Besides its cofactor function for activated protein C it has an anticoagulant effect via direct interaction with FVIIIa. Similar to the situation with protein C, genetically determined protein S deficiency results in an increased risk for thromboembolic complications.

2.2.3. *Fibrinolysis System*

The organisms needs an efficient and fast system to produce a clot in any case of violation of blood vessels. The generation of a fibrin matrix is also important for wound healing and inflammatory reactions. However, of equal importance is an efficient system for fibrin degradation. This fibrinolytic system is needed for the prevention of overshooting clotting, or at least, for recanalization and repair after thrombotic events. Intra- and extravascular fibrinolysis is also necessary for removal of the fibrin matrix along with the progressive “organization” during the healing of wounds and inflamed areas.

The main fibrinolytic system in the blood is the plasmin pathway. It is activated by the proteolytic cleavage of the proenzyme plasminogen [9001-91-6], M_r 93 000, a protein with a plasma concentration of about 2 µM (200 mg/L). In its N-terminal part plasminogen contains five characteristic domains, the so-called kringle domains, and the rest of the plasminogen molecule contains the active center of a serine protease. The kringle domains are important for the binding of plasminogen to fibrin and thus the interaction with the substrate of the activated enzyme. The activation takes place by cleavage between Arg_{560}-Val_{561}. The activation of plasminogen does not involve a complex cascade, such as the coagulation system. However, several physiologic pathways of activation exist. The most important pathway involves the tissue-type plasminogen activator (t-PA), which is synthesized predominantly in endothelial cells. The expression of t-PA can be enhanced by several mediators, the most important being thrombin. t-PA contains also two kringle domains, binds to fibrin and activates plasminogen. Further domains of t-PA, whose physiologic significance is not yet clear, are a so-called “finger” domain, which is also found in fibronectin, and a domain which is similar to epidermal growth factor. Another important physiologic plasminogen activator is the urokinase-type plasminogen activator (u-PA), which may be found as “pro-urokinase”, a single chain molecule (scu-PA), and the cleaved form urokinase, devoid of the N-terminal epidermal growth factor-like and kringle domain. The name pro-urokinase is somewhat misleading, since also this molecule has already some fibrinolytic activity. It has been speculated that pro-urokinase circulates bound to some “inhibitor”, which gets lost by binding to fibrin, where pro-urokinase can be readily further activated by proteolytic cleavage, e.g., by traces of plasmin. The fibrinolytic system is also activated by the so-called “contact activation” involving kallikrein and FXIIa, which is at least in part mediated by conversion of scu-PA to urokinase.

Plasmin is not only involved in fibrin cleavage, but has also a variety of other substrates [7]; of importance for hemostasis are the proteolytic cleavage of t-PA and scu-PA enhancing its own activation, and on the other hand the inactivation of coagulation factors V and VIII.

Plasmin can degrade both fibrinogen and fibrin at several cleavage sites. The result are several fibrin(ogen) degradation products of different size (X, Y, D, E). These fibrin(ogen) degradation products, particularly the large X-fragments, lead to a disturbance of fibrin polymerization and have thus an anticoagulatory effect. Fibrin degradation products (FDP) can be detected by several laboratory tests; specific tests are available for fibrinogen or fibrin degradation products. The demonstration of FDP in the plasma may be associated with an abnormal activation of fibrinolysis, e.g., during a disseminated intravascular coagulation. An isolated overstimulation, called hyperfibrinolysis can rarely be found in patients with certain tumors, e.g., prostate carcinoma. In diseases with a very strong inflammatory reaction, such as sepsis, pancreatitis, or polytrauma, a massive release of proteolytic enzymes from neutrophil granulocytes, particularly elastase, occurs which may contribute to intra- and extravascular fibrinolysis [5].

2.2.4. *Plasma Proteinase Inhibitors*

Most of the proteins involved in the coagulation and fibrinolytic system are proteolytic enzymes. These proteinases belong all to the class of serine proteinases. Their activity must be regulated because otherwise they would be a threat to the host that they are designed to protect. This problem has been solved, for instance, by the evolution of a series of proteins which decrease the activity of the proteolytic enzymes and which are called proteinase inhibitors (Table 4). These proteinase inhibitors are also class specific and therefore this chapter is dealing with proteinase inhibitors of serine proteinases. The inhibitors rapidly form tight stoichiometric complexes with proteinases in a substratelike manner which leads to inactivation of the proteolytic enzyme. Cleavage of the inhibitor may occur, if at all, at a much slower rate compared with a substrate. In the case of serine proteinase inhibitors, inhibition results from an interaction of the proteinase substrate binding site and a region of the inhibitor which is known as reactive site loop. In the case of canonical inhibitors like the kunins, the conformation of the reactive site loop is highly complementary to the surface of the enzyme and resembles a substrate bound to the specificity site [8], [9]. Unlike the Kunitz-type inhibitors, antithrombin has a reactive site loop which is not held rigidly by disulfide bonds but is able to swing in a hingelike manner. In the resting state, the reactive site loop projects away above the bottom of the serpin. When the reactive center docks with thrombin, the Arg393–Ser394 reactive site peptide bond is cleaved. At this stage, the complex is covalently linked. Normally, in the next step a substrate would dissociate after cleavage regenerating the active enzyme. In contrast, antithrombin remains linked to thrombin by one arm of the now cleaved reactive site loop. This arm becomes inserted into the body of the inhibitor as an additional β-pleated sheet. This leads to a stable complex in which the enzyme is crushed against the body of the inhibitor, distorting it, which results in irreversible inhibition [10]. It should be mentioned that α_2-macroglobulin is unique with respect to its completely different mechanism of inactivating proteinases and its ability to inhibit members of the four classes of proteinases [11].

Proteinases which initiate and amplify the coagulation and fibrinolytic systems are thought to have a restricted ability to cleave peptide bonds. Their role is to activate the zymogen of other components of the system usually by a single peptide bond cleavage. Proteinase inhibitors act to limit the activation by rapidly complexing key enzymes of the amplification system. However, they do not completely shut down the pathways, but rather inhibit systemic activation and thereby localise coagulation and fibrinolysis. The physiological importance of proteinase inhibitors may be seen from their relative plasma concentration. If one excludes albumin and immunoglobulins, about 20% of the remaining proteins are proteinase inhibitors. Although there are inhibitors of cysteine and metallo proteinases in plasma, most of the inhibitors regulate the serine proteinases. At this time, inhibitor concentrates of antithrombin III (AT III), α_1-proteinase inhibitor (α_1-PI), and C1-Inhibitor (C1-Inh) are commercially available. Therefore, these three inhibitors are described in the following.

Antithrombin III, AT III; M_r 58 000, [12], [13] is a single chain glycoprotein and a member of the serpin family. It is synthesized in the liver and circulates in plasma with a half-life of about 3 days. The primary structure exhibits 432 amino acid residues, six of which form 3 intramolecular disulfide bonds. The carbohydrate moiety of the protein contributes to the molecular mass by about 15%. The plasma concentration of AT III is about 2.6 μmol/L and the reference activity is given with 70-120%. Two isoforms exist in plasma, AT- α and AT- β. About 90% of the plasma AT III is present as the α-isoform. The two isoforms differ in their degree of glycosylation: the α-form exhibits four glycosylation sites, whereas the β-form lacks the carbohydrate at Asp135. AT- β has a greater affinity for heparin and for both the intact and injured vessel wall [14].

Antithrombin III is the major inhibitor of thrombin, factor Xa, and factor IXa but it also inactivtes factors XIa and XIIa as well as serine proteinases which do not belong to the coagulation system like plasmin, kallikrein, and complement C1.

Inhibition of proteinases by AT III is slow if compared other proteinase–proteinase inhibitor complex formation. The inhibitory action of AT III is greatly accelerated (about hundredfold) by heparin or related polysaccharides [15]. Among the most pertinent are heparan sulfate proteoglycans which are found on or underlying the vessel wall where anticoagulant activity occurs. While the order of magnitude of the rate enhancement for inhibition of thrombin, factor IXa, and factor Xa by antithrombin in the presence of heparin there is a fundamental difference in the mechanism of enhancement of inhibition. Thrombin inhibition is accelerated because the heparin chain provides a template to bring the reactive site of the inhibitor and the active site of thrombin in close proximity. This is observed with heparin oligosaccharides of size greater than 18 monosaccharide units but not for those of smaller size [16], Even though they are still inducing a conformational change in antithrombin which leads to the optimal inhibitory conformation of the reactive site loop [17]. The affinity of heparin to the thrombin-antithrombin (TAT) complex is much lower than to the free enzyme and heparin therefore dissociates from TAT complexes. The complexes are removed from circulation by receptors in the liver (half-life < 5 min). In contrast, accelerated inhibition of factor Xa is mainly achieved by the induced conformational change of AT III which is observed even with a pentasaccharide.

Antithrombin deficiency may be acquired or inherited. The pattern of inheritance is usually autosomal dominant (non-sex-linked) with levels of biologically active inhibitor around 40-70% of normal. Deficiencies of AT III but also of protein C and S are the most common known genetic causes for thrombosis. Venous thrombosis is a serious medical problem which affects annually one in thousand individuals causing morbidity and death. Commonly, antithrombin deficiencies are divided in two groups, type I and type II, based on the results from immunological and functional assays [18], [19]. Type I is characterized by a 50 % reduction of antigen (and activity) caused by heterozygous mutation of the gene. Homozygous AT III type I deficiency appears to be not compatible with life. Type II deficiencies are those cases where the antigen level is normal but functional activity is reduced (usually by a heterozygous mutation). Type II deficiencies are subdivided in mutations affecting the reactive site (RS), the heparin binding site (HBS). Acquired AT III deficiencies are due to either decreased liver synthesis, increased loss, increased consumption, or drug-induced.

α_1-Proteinase inhibitor, M_r 52 000, α_1-PI) is a single-chain glycoprotein and a member of the serpin family. It is synthesized primarily in the liver but also in mononuclear phagocytes, intestinal epithelium and kidney parenchyma. α_1-PI circulates in the blood with a half-life of 3-5 days and is cleared by the reticulo endothelial system. The primary structure exhibits 394 amino acid residues, containing one free cysteine residue and three carbohydrate side chains [20].

α_1-PI inhibits a large number of serine proteinases including trypsin, chymotrypsin, cathepsin G, plasmin, thrombin, tissue kallikrein, factor Xa, plasminogen, and neutrophil elstase. During acute phase response α_1-PI is upregulated in order to control neutrophil derived proteases at inflammatory sites. It is implicated that α_1-PI plays also a role in immune response which include inhibition of lymphocyte response to phytohemagglutinin, inhibition of chemotaxis, and enhancement of pokeweed mitogen driven IgG synthesis [21].

Protease inhibitor and individual alleles are named according to their isoelectric focusing characteristics (PI M, PI S, PI Z). In addition to the polymorphism at gene level, the protein exhibits microheterogeneity due to differences in glycosylation and N-terminal processing. Inheritance of α_1-PI alleles is autosomal codominant: Each allele contributes to the total serum concentration and overall isoelectric focusing pattern. Phenotypes are PI MM (two normal alleles) PI ZZ (homozygous inheritance of two defect Z alleles) and PI SS (homozygous inheritance of two defect S alleles) [22]. α_1-PI-deficiency affects about one in 6000 caucasian americans but only one in 40 000 to one in 100 000 black americans. 95 % of all α_1-PI-deficient patients belong to the PI ZZ which is characterized by a plasma level of 1.8 - 3.6 mg/mL (10 - 28 mg/mL for normal phenotypes, PI MM; threshold level for protection against lung damage due to proteolytic activity 10 - 12 mg/mL). Clinical manifestation of α_1-PI-deficiency is emphysema in adults and liver disease in children.

C1-Inhibitor, M_r 104 000, is a single-chain glycoprotein which belongs to the serpin family. It is mainly synthesized in the liver. Other sites of biosynthesis are skin fibroblast as well as monocytes. C1-Inhibitor circulates in the blood with a half-life of about 67 to 72 hours. Normal plasma levels are in the range of 0.2 mg/mL. The native molecule consists of 478 amino acid residues (including two disulfide bonds) and exhibits an unusually high carbohydrate content of about 50 % [23].

The inhibitor is involved in the regulation of several proteolytic systems including the complement (C1s, C1r), coagulation factor XIa, fibrinolytic (plasmin), and contact (factor XIIa, kallikrein) systems. Hereditary or aquired deficiency of C1-Inhibitor may result in accumulation of vasoactive substances. Sudden death due to acute larynx edema or nonitching, hard, painless swelling of soft tissues, and coliclike pains might result. In type I hereditary angioedema (HAE), an insufficient synthesis and elevated turnover of a normal C1-Inhibitor results levels of 5 - 30 % of normal. In type II, functionally inactive inhibitor is detected and the product of the normal allele is found in low concentrations. In aquired angioedema (AAE) type I, C1-inhibitor and C1 are diminished and in type II of AAE an anti-C1-Inhibitor autoantibody interferes with complex formation between enzyme and inhibitor [23].

2.2.5. *Immunoglobulins*

Immunoglobulins, also called antibodies (⟶ Immunotherapy and Vaccines – Antibodies) are produced by B-lymphocytes (see Section Leukocytes, Cytokins) (⟶ Immunotherapy and Vaccines – Immune Response). Their function is to “recognize” and bind specifically certain molecules, their corresponding antigens. The human organism possesses about 10^6 – 10^8 different antibody specificities and is thus able to react to a great variety of antigens. The immunoglobulins make up a specific humoral immunity and play an important role in the body's defense against pathogenic microorganisms and toxic substances.

As already outlined above, each B-cell carries its own specific immunoglobulin on the outer cell surface, which functions as an antigen receptor. If a certain antigen enters the organism, it binds selectively to corresponding antigen receptors (surface immunoglobulins) on B-cells. By this mechanism, B-cells, which are able to produce suitable antibodies, are selected and activated. Supported by cytokins produced by T-helper cells, a clonal proliferation and differentiation into plasma cells is initiated. The plasma cells produce and secrete high amounts of the specific antibody which mediates the humoral immune answer. The antibody production can last over different periods of time up to many years; in many cases, after the antibody production is down regulated, so called memory cells remain which may reside permanently in lymphatic organs and also may recirculate. By this mechanism, a fast and strong immune reaction can be initiated in case of repeated antigen exposure.

The basic structure of immunoglobulins is that of a Y-shaped four-chain polypeptide (Fig. 9). The polypeptide is a symmetric tetramer of two heavy (i.e., high molecular) chains and two light (i.e., low molecular) chains each. The C-terminal portion of these chains contains the so-called constant regions, while the N-terminal parts (the end of the two branches of the “Y”) have a very variable structure, which is responsible for the high diversity of binding properties corresponding to the numerous antigens, which can be recognized. The variability is brought about by gene rearrangements during the maturation of the B-cell precursors into mature B-cells (see [24]). While the two branches of the “Y”, also called Fab, contain the variable parts responsible for antigen recognition, the C-terminal part, called Fc, is important for effector functions of the immunoglobulins, e.g., complement binding and interactions with inflammatory cells. Immunoglobulins can be cleaved by enzymes like papain or pepsin, which can be utilized to produce fragments with particular characteristics (Fig. 10). Such a cleavage may be of interest in order to achieve a different distribution into body compartments of the Fab-fragments compared to intact immunoglobulins, but may also be utilized if only antigen binding, but not the effector functions mediated by Fc are required.

Figure 9. Schematic structure of immunoglobulin: V_L and V_H are variable regions, C_L and C_H constant parts of light and heavy chains

Figure 10. Products of enzymatic cleavage of IgG.

2.2.6. *Albumin*

Albumin is the most abundant plasma protein, with an average concentration of 36 – 50 g/L. It has a molecular mass of 66 000 and is the only plasma protein of this size without carbohydrate content. Albumin is synthesized by the liver. The half life of albumin is about 19 d, it is catabolized in many tissues and some loss occurs through the intestinal tract.

The most important function of albumin is to maintain the oncotic pressure, which is necessary to retain fluid within the vasculature against the hydrostatic blood pressure. While in the arterial part of capillaries the hydrostatic pressure is higher leading to extravasation of fluid, the hydrostatic pressure decreases towards the venous part of the capillaries below the oncotic pressure, which leads to an influx of fluid. This mechanism is of critical importance for the exchange of fluid and metabolites between the extra- and intravascular space and thus for the homeostasis of the body as a whole. Besides this function, albumin is a carrier protein for numerous substances, both physiological compounds as well as medications.

[Top of Page]

3. Production

As outlined in Chapter Composition, Physiology and Chemical Properties of Blood, there are numerous constituents of the blood that can be used as medicines. The majority of products on the market are derived from human blood. The use of animal material is for several reasons only of minor importance. Plasma proteins can be produced also by recombinant techniques, which is so far mainly used for coagulation factors for hemophilia treatment and for thrombolytic drugs.

3.1. Blood and Plasma Donation

The first attempt to transfer blood from one individual to another was in 1492, when blood from three young men was given to the Pope Innocent VII; unfortunately all four died [25]. Also trials with sheep blood were disappointing. A major step forward was finding a way to prevent clotting of the blood; the first nontoxic anticoagulant was sodium phosphate, which was found out by BRAXTON HICKS in 1869. Another breakthrough was the discovery of AB0 blood groups by KARL LANDSTEINER in 1901. Now the stage was set for further refinements and improvements in the collection, storage, and application of blood transfusions. This new medical discipline was strongly stimulated by World War II, when blood donation programs were developed, preservatives such as acid citrate-dextrose (ACD) were invented, and techniques for blood fractionation were developed. Of major importance for the development of a plasma industry was the work of COHN, who developed techniques for plasma fractionation (see Section Fractionation of Plasma).

The fundamental prerequisite for the manufacture of blood components and plasma derivatives remains the willingness of millions of people to donate their blood. One of the most important issues in the whole area is therefore the ongoing information, motivation, and protection of blood donors. Experience has shown that severe diseases, particularly infections with viruses such as human immune deficiency virus (HIV) can be transmitted by blood. In order to protect the recipients of blood products from such risks, careful selection of donors and testing of their donations is necessary. In order to ensure this, standards have been developed by organizations for blood collection (blood systems) and regulatory authorities, both on national and international levels. Although these standards are more or less comparable in developed countries, the organization of blood systems and the particulars of regulations and guidelines in this field may differ considerably not only from continent to continent, but also from country to country. Essential points of donor selection are the physical examination in order to verify a good health status, and an interview or questionnaire in order to find out whether there is any obstacle in the medical history or the behavior of the prospective donor. The latter point may be rather delicate, since, e.g., individuals with unsafe sexual behavior are not acceptable as blood donors.

If a donor is found suitable, the collection of his/her blood can start (in some countries the very first donation of an individual may be discarded as a measure of precaution). For the proper collection of blood, the rules of good manufacturing practice (GMP) have to be strictly followed. This includes suitable premises, well trained personal, and a quality assurance system. Crucial is the maintenance of hygiene from disinfection of the venipuncture site to a clean environment for processing and storage of blood components. The term blood components covers all blood-derived products for direct use as transfusion (e.g., erythrocyte or platelet concentrates, fresh or fresh frozen plasma). The blood is primarily collected into plastic blood bags. The collecting bags are usually centrifuged in order to produce different types of components. Numerous modifications exist, it is for instance possible to produce platelet concentrates from platelet rich plasma (supernatant of a “soft” spin of the blood) or from the so called buffy coat (white layer containing leukocytes and platelets on top of the red cells after a “hard” spin of the blood). In order to avoid a bacterial contamination of the products, the industry developed closed systems, i.e., a collection bag and additional bags in which the components can be transferred after separation, interconnected by appropriate tubes. For some special components it is necessary to open the system (an example is the addition of cryopreservatives to stem cells). For that purpose so called sterile connecting devices (SCD) have been developed which automatically cut and reconnect tubes with high temperature in order to avoid contamination. Of crucial importance for transfusion medicine is the careful documentation of the donation and all relevant data. The components must not be released before the negative results of safety relevant tests (serological markers for HIV and hepatitis B and C infections, additional parameters depending on the country) are available. Careful documentation and labeling is also necessary

because a confusion of components ("the wrong blood to the wrong patient") is a prominent cause of severe and potentially fatal complications.

Blood collection can also be carried out by apheresis techniques. This means, that a part of the blood is separated from the donation and the rest is given back to the donor. In the beginning, this was done by so called "manual" apheresis. An example was the manual plasmapheresis, where blood was taken from the donor and separated into plasma, which was used and the red cells which were retransfused into the donor. In the meantime techniques for "automatic" apheresis have been developed, which involve an extracorporal circulation of blood. In principle, blood flows from the donor via a tubing system into a machine, where a continuous flow differential centrifugation takes place with outlet tubes leading the desired component(s) into collection bag(s), and the rest of the blood back to the donor. By this way plasma can be obtained, as well as cellular components such as platelets or stem cells or erythrocytes.

The above described collection techniques may be used to obtain both blood components for transfusion and source plasma for the manufacture of plasma protein concentrates. The origin of the source plasma, i.e., donor population (geographical and epidemiological background), technique of collection (recovered from whole blood or plasmapheresis) and handling (freezing, storage, transport) may have significant impact on the quality of this important raw material. In order to enable the production on an industrial scale, source plasma is usually pooled; the size of these plasma pools varies considerably according to the facilities used and the product and can be up to several ten thousand donations. The fractionation of these plasma pools is described below.

3.2. Substances Derived from Blood Cells

Some attempts were made in the past to produce crude blood cell extracts or homogenates for medicinal purposes. These preparations are poorly characterized and have been part of alternative medicine in some countries.

However, there are also some examples for specific medicines derived from blood cells. From blood leukocytes β-interferon can be obtained (⟶ Interferons – Natural Leukocyte IFN). A preparation of hemin (derivative of the heme obtained from the hemoglobin of outdated erythrocytes), is used in severe hepatic porphyrias. An old desire in medicine, which had a renaissance in context with the experience of HIV transmission by blood products, is to find blood substitutes, which means nonerythrocyte oxygen carriers. Besides several synthetic substances such as perfluorocarbons, a current approach is to use modified or cross-linked hemoglobins. A limitation of this approach is that higher concentrations of free hemoglobin may be toxic, e.g., for the kidneys. Besides their capacity to transport oxygen, the hemoglobin-based blood substitutes appear to have also some impact on vascular tonus and blood pressure and other indirect effects; such effects may be of therapeutic use.

3.3. Fractionation of Plasma

3.3.1. *Quality Requirements*

In any kind of medical therapy, assessment of the risk-benefit as well as the development of therapeutic standards is an important consideration for the use of a medicinal product. Historically, in the case of hemophilia patients substitution therapy with plasma or plasma-derived products was of such a life-saving importance that other aspects were not considered adequately. However, with the HIV catastrophe this attitude has changed and virus safety of plasma and plasma derived products are issues of highest priority in health policy, the medical community, and the public interest. Although virus safety is obviously of major interest, besides the transmission of viruses and other hitherto unknown pathogens, possible other safety aspects must be considered. Examples are the development of antibodies (inhibitors) to plasma components and the risk of thrombogenicity due to the administration of activated coagulation factors.

In general, the whole manufacturing process contributes to the quality of a product. In the case of blood preparations, this process already starts with the collection of the source material, plasma for fractionation. Measures taken are the selection of donors, testing of single donations and subsequently pooling of single plasma donations to plasma pools, testing of the plasma pools, and the selection of suitable methods for the purification including virus inactivation/elimination steps. All manufacturing steps should be performed under validated conditions and according to cGMP yielding a product of consistent quality, safety, and efficacy. Regulatory approaches in different continents are still not entirely harmonized but their essential elements are similar. For the EU, the blood and plasma collection for both the manufacture of plasma for transfusion and plasma for fractionation is regulated by Directives [26], whereas the quality standard for plasma for fractionation, e.g., quality attributes, viral marker testing of plasma pools as well as freezing, storage, and transport conditions are provided by the monograph "Plasma for fractionation" of the European Pharmacopoeia (Ph. Eur.) [27]. In addition, there are monographs for plasma derived products available, e.g., human Factor VIII, Factor IX, Prothrombin Complex Concentrates, Fibrinogen, Albumin, Immunoglobulins, etc. setting quality standards for these products. Monographs are legally binding documents. Guidelines of the Committee for Medicinal Products for Human Use (CHMP), the scientific working arm of the European Medicines Agency (EMEA) in London [29] and its working groups, e.g., the Biological Working Party (BWP), provide further guidance on the manufacture of plasma derived medicinal products [28]. These guidance documents consider all steps in the manufacture of a plasma-derived product with a focus on infectious pathogens.

3.3.2. *Preparation of Intermediate Products*

Typical examples of plasma fractionation leading to low or intermediate purity are the Cohn fractionation procedure or derivatives thereof [30]. This technique is up to now in use for the production of major protein constituents of plasma (e.g., albumin and immunoglobulins). The Cohn fractionation takes advantage of the different physicochemical properties of proteins resulting in their different behavior at a given temperature in aqueous solutions of differing pH, salt, and alcohol concentration (see Fig. 11). For the purification of less abundant components it is now a widely common technique to separate plasma into the cryoprecipitate (obtained by thawing frozen plasma at or around 4 °C) and into so-called cryo-poor plasma (proteins which stay in solution after this procedure). Redissolved cryoprecipitate has long been in use for the treatment of hemophilia A, because coagulation factor VIII is enriched in this plasma fraction. Cryoprecipitate is also used as a source for fibrinogen which may then be marketed as tissue glue (in combination with thrombin). The cryo-poor plasma fraction is up to now in use for the preparation of intermediate-purity products, such as immunoglobulins, albumin, and

prothrombin complex concentrates (PCC). A derivative of the latter is activated prothrombin complex (aPCC) marketed as factor eight inhibitor bypassing activity (FEIBA) or Autoplex. PCC has long been used for the treatment of, e.g., hemophilia B while it is now occasionally in use for the treatment of acquired coagulation disturbances (e.g., reversal of anticoagulation by treatment with Marcumar during surgery). Activated PCC is given in certain cases of hemophilia A to patients with inhibiting antibodies against FVIII. The PCC is obtained from cryo-poor plasma by batch adsorption to anion-exchange media at relatively low pH, followed by washing and step elution of the coagulation factors. In some protocols a barium citrate precipitation step (or similar) is included in the process. Essentially the same procedure is performed for the preparation of Autoplex (FEIBA), followed by an activation step in order to obtain (among others) activated FVII.

Figure 11. Cohn fractionation of plasma.

Plama fractionation according to Cohn and co-workers Plasma is fractionated by stepwise adding ethanol, adjusting pH, and/ or dilution. Although not illustrated here, the temperature is also carefully controlled. Each step (the corresponding designations in the figure are as in the original article) is followed by removing the resulting precipitate. The individual precipitates contain mainly fibrinogen (no. I), β-, γ- globulin, and prothrombin (no. II/III), α-globulin (no. IV-1), α-, β-globulin (no. IV-4), and albumin (no. V).

3.3.3. *Purification of Plasma Proteins*

The Cohn fractionation is up to now in use for the preparation of albumin and immunoglobulins, representing the major constituents of plasma proteins. Since the late 1980s, however, have not only analytical techniques been very much improved, but the same is true for preparative applications. Typical examples are FIX and FVIII high-purity concentrates which are now available. Both coagulation factors are characterized by their relative scarcity as compared to albumin and immunoglobulins. These novel developments became available through the now widespread use of affinity chromatography (see Section FVIII High Purity Concentrates.) as well as novel chromatography media and column designs (e.g., radial flow technology) allowing higher flow rates, thus shortening the purification process.

FIX High-Purity Concentrates. In contrast to PCC — the therapeutic for the treatment of hemophilia B in former years — FIX is purified by gradient elution of proteins from anion- exchange columns, followed by adsorption to at least group specific affinity columns, e.g., heparin or dextran sulfate modified media. Also in use are chromatography techniques employing immobilized monoclonal antibodies. These techniques lead to purities such that the target protein is at least the major component in these products.

FVIII High Purity Concentrates. Compared to high purity FIX concentrates the purity of so-called high purity FVIII concentrates is much less striking. This, however, is not surprising, considering that on a molar basis FIX is hundred-fold more concentrated in plasma than FVIII (see below). One major contaminant in several commercially available concentrates is serum albumin which is added after purification in order to stabilize FVIII. Beginning with cryoprecipitates, FVIII is purified using anion-exchange chromatography, in certain cases followed by affinity chromatography on monoclonal antibody media. Alternative purification strategies take advantage of the association of FVIII with von Willebrand factor. Being an unusually large protein complex, this association was successfully subjected to size exclusion chromatography, a technique which is normally characterized by poor resolution.

Although not a purification step, it should be mentioned here that for safety reasons all medium- or high-purity products on the market are subjected to two complemantary virus inactivation steps (e.g., heat treatment or solvent detergent treatment) prior to or after filling of the final containers. Before this procedure is performed the proteins are transferred into a buffer system capable of stabilizing the fragile coagulation factors. These stabilizing additives (mainly sugars and/ or amino acids, albumin) represent a contamination. Similarly, antithrombin III and/ or heparin are added to certain coagulation factor concentrates. This step is performed to prevent activation of coagulation factors or to inactivate those which were converted to proteases during production. These components may be considered a contamination, at least from a biochemical view. Generally, the purification of proteins for therapeutic use is considered to be beneficial by removing possibly hazardous contaminants. However, the procedures performed during purification may also be detrimental for the proteins to be purified. This may hold true especially for the purification of coagulation factors as many of these are progenitors of proteases and must not be activated, otherwise the therapeutics may lead to thromboembolic complications. Also, they are extremely sensitive against denaturation (due to their multi-subunit structure as in the case of, e.g., FVIII). The denaturation may lead to the formation of neoantigens which in turn will cause the development of inhibiting antibodies.

3.4. Recombinant Proteins

In order to circumvent the risk of contamination of coagulation factor preparations by human pathogens (Transmittable Pathogens) recombinant gene technology has been introduced for the production of several therapeutics instead of purifying these from human plasma. Recently, certain member states of the European Union (Ireland, UK, Sweden) have decided to use recombinant coagulation factors exclusively where available. Among others, FVIIa, FVIII, and FIX have been cloned and expressed in eucaryotic cells of nonhuman origin from which they can subsequently be purified. The purification strategies follow the same procedures as outlined above for the purification from human plasma to yield products free of human viruses. However, recently the problem of other pathogens has become apparent. At least during the initial phase of eucaryotic cell cultivation serum of animal origin is needed for feeding, thus raising the risk of contamination by nonhuman pathogens which eventually will adapt to the new host. Moreover, there is a theoretical risk that potentially novel pathogens may contaminate recombinant protein preparations. Here, prion proteins, the putative causative agent of bovine spongiforme encephalitis (BSE) or Creutzfeld Jacob disease in man (CJD) should be mentioned [31]. In addition, due to the expression in cells of nonhuman origin, posttranslational modifications may differ in proteins from recombinant sources which eventually lead to the recognition of these products as foreign and the development of antibodies against these agents. Apart from producing recombinant proteins in vitro in eucaryotic cells, expression systems have been developed which allow the production in living animals where the proteins of interest are delivered into the milk and can be purified from this source.

3.5. Adverse Drug Reactions of Blood Products

3.5.1. *Immunogenicity*

Proteins are increasingly used as therapeutic agents (see ⟶ Enzymes – Nonindustrial Enzyme Usage and ⟶ Enzymes – Therapeutic Enzymes). It has been recognized that these medicinal products frequently induce an immune reaction leading to antibody formation. The consequences of an immune reaction to a therapeutic protein range from transient appearance of antibodies without any clinical consequences to severe life threatening conditions. Potential clinical consequences are severe allergic reactions, reduction of efficacy, and induction of autoimmunity, including antibodies to the endogenous protein. Of further concern is the interference of antibody formation with clinical parameters, e.g., recovery, residence time, and the laboratory assays to measure the therapeutic protein [32], [33], [34].

Many factors may influence the immunogenicity of therapeutic proteins. They can be considered to be patient-, disease-, or product-related. Patient-related factors might predispose patients to an immune response, e.g., genetic background, ethnic origin, immune and infection status, and treatment with immune-suppressive medicines. Disease-related factors include various immune disorders. Product/treatment-related factors might also influence the likelihood of an immune response, e.g., intensity of treatment (dose frequency, duration of treatment), route of administration, source of protein (human or animal or recombinant origin), manufacturing process (contaminants, impurity profile), formulation and stability characteristics (degradation products, aggregates) of a given protein.

Development of antibodies against blood components is of special importance for the blood coagulation factors VIII and IX which are used for the treatment of hemophilia A or B patients [35]. These events are the most serious complications during the treatment of hemophiliacs besides the possible transmission of blood-borne pathogens. The antibodies, also called “inhibitors”, can interfere with the biological function of the coagulation factor [36] or can enhance for example the clearance of the coagulation factor [37]. Both events can lead to life threatening complications for the patients. Patients who develop inhibitors are classified as low or high responder according to the level of antibodies. Low responders are those who produce a low level of inhibitor (< 5 B.E.) and who do not react with an increase of inhibitor in case of new coagulation factor injections. High responders are those patients with a high titer of inhibitor (> 5 B.E.) and who react with an increase of inhibitor in case of new coagulation factor injections. Low responders can be treated with higher doses of the coagulation factor concentrate which overcome the inhibitor, whereas for the treatment of high responders other therapies like treatment with factor VIIa or activated prothrombin complex concentrates have to be considered.

Antibodies directed towards functional epitopes of the factor VIII molecule are currently evaluated in vitro by their capacity to inhibit the procoagulant activity of plasma factor VIII. Quantitation is obtained by mixing/incubating dilutions of the inhibitor containing plasma with a fixed amount of factor VIII. The active amount of inhibitor, expressed in units per milliliter plasma, is the reciprocal of the plasma dilution that neutralizes factor VIII activity. For routine analysis, the New Oxford assay (source of factor VIII is a concentrate) and the Bethesda method (source of factor VIII is a pooled normal plasma) have been used [38], [39]. It is now recommended to use a modification of the Bethesda method by which the progressive decrease of pH during incubation is prevented, which can lead to false positive results [40]. Inhibitors can also be detected independent of their functional activity using enzyme-linked immmunosorbent assay (ELISA) techniques.

Inhibitor development against the substitutive product is considered to be due to either the type of substitute or the severity of hemophilia. Patient-related factors for the development of antibodies are poorly understood and a relationship between gene defect and inhibitors is not manifest. Results for hemophilia A patients, however, point out that patients with severe gene defects are more prone to inhibitor development, perhaps due to the absence of circulating factor VIII and the lack of immune tolerance induction [41], [42]. Product-related factors could also be responsible for inhibitor development which was observed in hemophilia A patients treated for several years with factor VIII products without developing inhibitors. When these patients had been exposed to a certain factor VIII product, they developed inhibitors after a variable length of exposure days [43].

3.5.2. *Thrombogenicity*

Thromboembolic complications are the major adverse events during the treatment of patients with prothrombin complex concentrates (PCCs) [44-47]. Prothrombin complex concentrates contain the coagulation factors II, VII, IX and X, protein Z, as well as the coagulation inhibitors protein C and S. These products are indicated for the treatment of patients with decreased levels of factors of the prothrombin complex due to vitamin K deficiencies, overdosing of oral anticoagulants, e.g., vitamin K, or decreased synthesis caused by liver dysfunctions. The three component PCCs (factor II, IX and X) have previously been used for the treatment of hemophilia B but have been replaced by high-purity factor IX concentrates or recombinant factor IX. Different from PCCs are those products (FEIBA, Autoplex) which contain activated factors of the prothrombin complex and which have another indication.

Prothrombin complex concentrates are standardized with respect to their factor IX content. According to the Ph. Eur. monograph [27], PCCs should exhibit an equal composition of the prothrombin complex factors and their content of protein C and S should be indicated. In addition, most of the PCCs have heparin and antithrombin III added. PCCs have to comply with requirements of the nonactivated partial thromboplastin time and the thrombin fibrinogen clotting time. As these parameters, however, have been found to be of low predictive value with respect to in vivo correlation, additional measures should be followed by the treating physician in order to minimize the risk of thrombotic complications [46], [47].

During a 4-years survey from 1987 to 1990, 72 case reports on complications with PCCs were published [48]. Major risk factors of thrombogenicity have been reported to be (1) predisposing factors, i.e., the patient's underlying disease; (2) therapy factors, i.e., dosage (zymogen overload leading to a prothrombotic state) and concomitant therapy; and (3) quality of the PCCs. With respect to the quality aspect of PCCs, activated coagulation factors II, VII and IX as well as the absence or low levels of antithrombin III and protein C and S have been discussed to cause the clinical signs of thrombogenicity which manifest as phlebitis or venous thrombosis, pulmonary embolism, cerebral or myocardial infarction, disseminated intravascular coagulation with bleeding, and organ failure due to consumption of coagulation factors and fibrin formation. Coagulant active phospholipids, which have been detected in PCCs, were also discussed as potent thrombogenic triggers potentiating the effect of activated coagulation factors [49]. During the last few years, scientific data were accumulating which showed without a doubt that prothrombin overload is causing thromboembolic complications while treating patients with

PCCs [50-52].

3.5.3. *Transmittable Pathogens*

One immanent risk of blood products is the transmission of pathogens. This issue is therefore of particular concern and appropriate measures have to be taken by the manufacturer to prevent the transmission of infections by the use of plasma-derived medicinal products [53]. Those pathogens include HBV, HCV, HIV-1 and HIV-2, HAV, and Virus B19. During the recent years, emerging pathogens, e.g., variant CJD (vCJD) and West Nile virus (WNV) had to be added to this list of pathogens with importance for the safety of blood products. Therefore, the collection of the source material, plasma for fractionation, is of great importance in the assurance of the quality and safety of medicinal products derived from blood. Factors which should be considered for the collection of plasma (blood) include various factors like suitability of donors, screening of donations and epidemiology of the population from which plasma is collected. The risk assessment for medicinal products derived from plasma (blood) should consider the amount of virus which may contaminate the manufacturing plasma pool versus the capacity of the manufacturing process to remove or inactivate the pathogens. By considering the amount of starting material needed to manufacture a single dose of product, the probability of potential virus contamination can be estimated [54].

A recently emerged infection in North America is the WNV which belongs to the *Flaviviridae* family. Clinical symptoms in humans occur 2-14 days after infection and viraemia within 1-3 days after infection and lasts 1-11 days. Thus, an infected person could be viraemic before symptoms are seen. As mentioned above, the viral safety of plasma-derived medicinal products involves several approaches and re-evaluation those for the purpose of WNV lead to the assurance that the measures in place today are adequate to assure viral safety of plasma-derived products with respect to WNV [55].

Tracing recipients of blood transfusions from donors who subsequently developed vCJD has revealed possible cases of secondary transmission. This finding is consistent with the observation for sheep transfusion studies that infectivity in blood can be transmitted during preclinical phase of infection. To date many studies have been performed, which investigate the contribution of various manufacturing steps to reduction of infectivity. However, caution is needed in interpretation of the data since the effectiveness of a step is dependent on a number of variables, e.g., process conditions and state of the agent in the sample. Consequently, effectiveness of removal may vary from process to process. As vCJD is an emerging disease, uncertainties still exist about the number of cases of vCJD that will occur and the transmission of the infective agent by blood donations. Today, no screening test is available and therefore approaches are considered to identify donors who may present a higher risk. Therefore it is recommended to exclude donors who have spent a cumulative period of one year in the United Kingdom from donating blood/plasma for fractionation. In view of the lack of adequate information on vCJD, it is prudent to recall batches of plasma-derived medicinal products where a donor to a pool subsequently develops vCJD. Also medicinal products containing plasma-derived products as excipient should be recalled [56]. This issue is kept under review of the CHMP and its working groups.

[Top of Page]

4. Therapeutic Uses

Medicines derived from blood and plasma play an important role in the medical therapy in general. In most cases, they are used to replace the respective components or proteins in case of their loss or insufficient production. Particularly, the development of contemporary surgery, which is often associated with blood loss, would not have been possible without the possibility of transfusion. Also in hematology and oncology, and of course in the treatment of bleeding disorders, blood products are indispensable.

4.1. Blood Components

4.1.1. *Blood and Stem Cell Preparations*

Erythrocytes. The most important components in terms of the amounts used and the potentially immediate life-saving effect are those containing erythrocytes. Whereas initially whole blood was the mainstay of hemotherapy, nowadays erythrocyte concentrates are prevailing. These concentrates are conventionally produced from whole blood donations by centrifugation, and can be obtained also by modern apheresis techniques. With contemporary additives, erythrocyte concentrates may have a shelf life of up to 7 weeks. It is a well-documented experience [57] that immunization of blood recipients against donor antigens is mainly mediated by contaminating leukocytes. Immunization can cause severe allergic reactions or impair the therapeutic effect to subsequent transfusions. Also other unwanted effects of transfusions have been attributed to their leukocyte content. Thus, “leukodepletion”, the removal of leukocytes by filtration or modification of apheresis, is increasingly recommended, despite the increase of expenses for the concentrates.

There are several guidelines [59], but no rigid rule regarding the indication for erythrocyte transfusion. In every individual patient, the indication should be considered carefully. For instance, young, otherwise healthy patients tolerate lower Hb-levels than elderly patients, particularly those with cardiovascular disorders. Chronic anemia is far better compensated than acute blood loss. Therefore, the conventional recommendation of 10 g/dL Hb and below as a trigger for transfusion is at best a rough “rule of thumb”.

Platelets. A lack or functional disturbances of thrombocytes lead to a severe bleeding tendency. The typical clinical pattern is petechiae and bleeding from mucous membranes (e.g., nose, gingiva) but also life-threatening CNS bleedings. A bleeding tendency may be present at thrombocyte counts around 30 000/µL; a clear increase of the bleeding risk necessitating platelet transfusions occurs below 10 000/µL. Functional disturbances may be inherited such as defects of GP IIb-IIIa (thrombasthenia Glanzmann), or of GP Ib-IX (Bernhard Soulier Syndrome). More frequent are acquired functional defects in liver disease or renal insufficiency, or by medications such as analgesics or antibiotics. On the other hand, platelet inhibition may be a target of therapy in thromboembolic diseases, particularly in arterial events such as myocardial infarction or stroke. The classical substance for platelet inhibition is aspirin, but a number of new substances against specific receptor pathways are currently developed and evaluated.

Leukocytes. The use of leukocyte (e.g., granulocyte) concentrates is still restricted to very special circumstances, since considerable problems occur with unwanted effects, e.g., acute lung injury.

Stem Cells. An increasingly important field is the production and use of hematopoietic stem cells [61]. Stem cells can be obtained from aspirated bone marrow, from peripheral blood by apheresis, and from placenta via the umbilical cord; also fetal liver contains stem cells. Currently, the most important use is for "rescue" of hematopoiesis after otherwise lethal chemotherapy and/or radiation for treatment of several malignancies, or after damage or aplasia of the bone marrow (bone marrow or stem cell transplantation). Also "autologous" stem cells taken from the patient and reinfused after intensified antineoplastic treatment are in use; strategies are developed to purify the CD-34 positive stem cells, or to remove malignant cells ("purging") from the preparation. Still in the experimental stage are approaches to augment the stem cells in culture ("ex vivo expansion"), or to manipulate them by incubation with antigens and cytokins in order to obtain a specific immunological therapy. Of so far unforeseeable importance are stem cells as a vehicle for gene therapy.

4.1.2. *Fresh Frozen Plasma*

Most of the whole blood donations are separated into cells and plasma; plasma can also be obtained by plasmapheresis (see Section Blood and Plasma Donation). Plasma can be used as source for industrial production of protein concentrates, or as a component for direct transfusion. For the latter purpose, plasma is usually rapidly frozen as soon as possible (fresh frozen plasma) and stored in a freezer in order to preserve the sensitive proteins such as coagulation factors.

Plasma as a therapeutic component has the advantage that it is the physiologic fluid part of blood with a balanced content of proteins, particularly albumin, coagulation factors, inhibitors, and immunoglobulins, as well as electrolytes and other natural constituents. Therefore, plasma is in principle an ideal substitute in case of blood loss, in combination with red cells as clinically appropriate. However, it is no more recommended to use plasma just for volume replacement, since it is available in limited amounts only, and since alternatives, so-called "plasma expanders", e.g., dextrans or hydroxyethyl starch, are available. Moreover, plasma still carries a low residual infectious risk; there are strategies to keep plasma in quarantine until the donor is tested again after at least 6 months, to exclude the possibility of donations during the diagnostic window, i.e., the time between infection and the detectability of virus markers. There are also attempts to apply virus inactivation steps to single donations, or to pooled plasma, which is subsequently divided again into units of the usual size.

The main indication of plasma transfusion is the prevention and treatment of profound and complex disorders of blood coagulation, such as consumptive thrombohemorrhagic disorders, in surgical and intensive care patients. In the treatment of those disorders, e.g., disseminated intravascular coagulation, a multitude of factors and inhibitors are consumed, and plasma may be a suitable way to replace all of them in a balanced way. Large volumes of plasma may have to be transfused in order to obtain relevant replacement in full-blown consumption, potentially leading to fluid overload; some clinicians use therefore concentrates alone or in combination with plasma. The therapy of such complex disturbances, however, is far from being standardized, and should be directed by experienced specialists taking into account the individual clinical picture. In the treatment of hemophilia or other single-protein deficiencies, suitable concentrates should be used. In general, the indications for plasma transfusion are hard to define, and should be further evaluated in clinical studies.

4.2. Hemoglobin-Derived Oxygen Carriers

The driving forces behind the development of "artificial blood" are the avoidance of the risk of infection by allogeneic blood transfusion, and to overcome the problems posed by blood grouping and the limited shelf life of erythrocyte concentrates. In fact, hemoglobin isolated from blood, which may be modified e.g., by cross-linking, is capable of effective oxygen transport. These preparations may elicit also some increase of blood pressure, which might be interesting in particular circumstances.

The original hope to have a new, virtually unlimited source of oxygen carriers which would supersede conventional blood components has been darkened so far by the finding of substantial toxicity of larger doses of these carriers. Free hemoglobin outside the "parent" erythrocytes is bound to a specific transport protein, named haptoglobin, and has to be cleared from the circulation. If the capacity of haptoglobin and the clearance system is exhausted, free hemoglobin is excreted via the kidney, and may lead to kidney failure similarly as in the case of massive myoglobin release in severe trauma ("crush kidney"). Also the new hemoglobin-derived substances are still limited in their dose. It might turn out that they have a potential in the emergency ambulance, e.g., for immediate on-site resuscitation of accident victims. Hemoglobin-derived substances are also evaluated for other indications, e.g., oxygen delivery and pressor effect in septic shock, or sensitization to radiotherapy in cancer patients. However, the intriguing approaches appear to need substantiation by further research.

4.3. Cytokins

A growing number of cytokins have effects of potential therapeutic interest (see Section Leukocytes, Cytokins and Table 2). Here, only some examples already in clinical use are mentioned.

One of the first therapeutic cytokins was interferon (⟶ Interferons), due to its antiviral and potential antineoplastic effects. Interferon is used in chronic viral hepatitis and may lead to clinical remission in part of the patients [63]. It is not a universal antitumor drug, but in several malignancies, e.g., in chronic myeloid leukemia, interferon is a valuable part of the therapeutic repertoire.

Increasingly used in hematology and oncology are also the hematopoietic growth factors such as G-CSF or GM-CSF. The may be useful to stimulate granulopoiesis in patients during the aplastic phase after chemotherapy, and also for "mobilization" of stem cells from the bone marrow in order to harvest them by apheresis. A new, promising, substance is thrombopoietin, which stimulates platelet production. Another substance which is conventionally classified as a hormone should also be mentioned here: erythropoietin, which is physiologically produced by the kidneys. Recombinant erythropoietin has proved to be of great value for patients with chronic renal failure, which used to be dependent on transfusions before. Erythropoietin is also used in certain hematological disorders.

4.4. Coagulation Factors

Congenital coagulation factor deficiencies mostly affect the level of a single factor, while acquired deficiency (e.g., due to impaired synthesis in liver disease, loss or dilution of blood, or consumption in sepsis) includes usually many or all factors. All coagulation factors are contained in plasma, which may be used for the treatment of complex factor deficiencies (see Section Fresh Frozen Plasma), concentrates are recommended in cases where specific factors are to be administered. This concept of a targeted therapy helps to avoid fluid overload, and an unwanted and possibly overshooting increase of factors which are normal or even elevated at baseline. This chapter covers treatment of congenital, one-factor deficiencies. There is a trend to high purity concentrates, since the lacking factor can be substituted in a more controlled fashion, and impurities are kept low. Such impurities could be associated with unwanted effects, such as immunosuppression, or thrombogenicity [65], [44].

The classical indication for the use of concentrates are the hemophilias A (lack of factor VIII), and B (lack of factor IX). Both are congenital disorders mediated by X-chromosomal inheritance, and thus affect almost exclusively males. The disease can be expressed with different severity depending on the underlying gene defect; the severe hemophilias (levels of < 1 % of the normal plasma level) are usually manifested already in early childhood, when the babies start crawling and moving around and thereby may hit themselves mildly, which would be easily compensated by a healthy coagulation, but may lead to severe bleeding in hemophiliacs. The typical symptoms are large hematoma of the skin, and bleeding into muscles and joints; bleeding at other sites including the particularly life-threatening central nervous system bleeds also occur. The frequency of hemophilias is about 1 in 10 000 males. Being a congenital defect, hemophilia necessitates life-long treatment. The therapy may be given in case of symptoms (“on demand treatment”), many patients with severe hemophilia are substituted with a fixed continuous schedule of usually two to three injections per week (“prophylactic treatment”); a typical prophylactic single dose would be 30 iU per kilogram of body weight.

While during the early 1980s a disastrous epidemic of HIV infections, transmitted by coagulation factor preparations, hit the hemophiliac population, the safety of the concentrates has been increased fundamentally in the meantime by careful selection and testing of blood donors, and virus inactivation procedures. Currently, the most important problem of treatment is the occurrence of so-called “inhibitors”, which means neutralizing antibodies, during therapy. These inhibitors usually occur during the initial phase of treatment around the 10th to the 20th exposure to the factor, which is “strange” to the recipient's immune system. The inhibitors only rarely cause allergic symptoms (predominantly those against factor IX). Therefore they may develop unnoticed and may cause severe problems in case of bleeding episodes, since the effect of the transfused factor is impaired or even blocked. It is recommended to check the patients regularly for inhibitors, particularly during initial treatment. Inhibitors occur much more often in hemophilia A, which is also the far more frequent form of the hemophilias. The treatment of such inhibitor patients has two aims: (1) to stop and control acute bleeding and (2) to eliminate the inhibitor. For stopping and controlling of bleeding, high doses of the involved factor, PTC, “activated” PTC, or (in hemophilia A patients only) porcine factor VIII or, as a newer approach, recombinant factor VIIa are in use. For the elimination of inhibitors, also referred to as “immunetolerance treatment”, prolonged treatment with frequent and high doses of factor VIII (“Bonn protocol”), as well as a combination with extracorporal removal techniques and immunosuppressive treatment (“Malmö protocol”) have been developed [66]. The elimination of factor IX inhibitors is particularly problematic, since allergic and anaphylactic reactions and, in case of high doses of factor IX, immune complex disorders such as nephritis [67] may develop. The occurrence of inhibitors is a frequent problem (in hemophilia A in up to 50 % of patients). In two clusters, inhibitors with unusual characteristics were associated with certain products [68], [43], which had to be taken off the market.

Another congenital bleeding disorder, which is even more frequent than hemophilia, is von Willebrand disease. However, since there are a lot of different mutations and thus functional and clinical categories, the classification of severity and the therapeutic consequences are much less clear-cut than in the hemophilias. A lack or dysfunction of von Willebrand factor may lead to a reduction of factor VIII levels and/or disturbances of platelet adhesion; the clinical symptoms resemble in many cases more a platelet defect with prolonged bleeding time, petechiae, and mucous membrane bruising. Since the inheritance is autosomal (chromosome 12), both sexes are equally affected. It is strange that the clinical severity may differ from one affected family member to the other, and even during time course in an individual. By far the most patients have mild symptoms, and it is not unusual to detect the disease in an adult. Mild forms may be treated with a vasopressine analogue (DDAVP), which mobilizes residual von Willebrand factor from its production site, the endothelial cells; this therapy is effective only a limited time (several days). In any case, an accurate diagnosis should be established first, and the effect should be evaluated in a test treatment, before, e.g., surgery is to be covered by DDAVP; in some forms of dysfunctional von Willebrand factor DDAVP may even be contraindicated. In some countries, factor VIII concentrates containing von Willebrand factor are registered for substitution in severe forms of von Willebrand disease.

Other congenital coagulation factor deficiencies are less frequent or even rare; an example is factor XIII deficiency with an estimated prevalence of 1 in 1×10^6 people. Factor XIII is a fibrin-stabilizing factor, which is important to make clots stable and resistant against premature fibrinolysis. Characteristic symptoms are umbilical cord bleeding of newborns, repeated re-bleeding after initial hemostasis, wound healing disturbances and spontaneous abortions. Unfortunately, there is a quite high frequency of central nervous system bleeds. In the past, a concentrate had been manufactured from placenta; nowadays, for treatment, a plasma-derived concentrate is registered in some countries. The significance of an acquired factor XIII deficiency needs further elucidation; there are intriguing data pointing to a role of factor XIII in wound healing [69].

4.5. Plasminogen Activators

Plasminogen activators are used in the thrombolytic therapy of severe thromboembolic disorders such as myocardial infarction and lung embolism. The physiologic task of the fibrinolytic system is the prevention of an overshooting clotting. However, if clinically significant thrombosis occurs, the natural fibrinolysis may take considerable time (several months) in order to remove the fibrin in the thrombus. In many cases, the thrombus is perpetuated by “organization”, i.e., the conversion into a connective tissue “scar”. Particularly in emergencies like myocardial infarction, a very fast recanalization is needed.

The first, and still widely used substance was streptokinase, a plasminogen activator derived from streptococci. Streptokinase forms a complex with a plasminogen, and this complex activates free plasminogen to plasmin. The disadvantage of streptokinase is mainly its antigenicity. Also a number of physiologic plasminogen activators exist, and numerous attempts have been made to modify them by recombinant techniques. The most widely used are urokinase and t-

PA. While urokinase, similarly as streptokinase, produces free plasmin leading to a massive degradation of fibrinogen and coagulation factors and thus to a pronounced disturbance of coagulation, t-PA acts predominantly at the fibrin clot and has therefore also been named a “fibrin specific” thrombolytic agent. The initial hope that this would reduce bleeding complications was not fulfilled at the high t-PA doses needed for rapid thrombolysis. However, t-PA appears to act somewhat faster than the other thrombolytic agents which might be an advantage in certain emergencies. However, urokinase and particularly t-PA are very costly.

Compared to a thrombophilic state due to a congenital deficiency of coagulation inhibitors (see Section Inhibitors), inherited disorders of the fibrinolytic system are much less frequent and the clinical significance is less clear. Though there are some reports about an enhanced thrombotic risk for individuals suffering from disturbances of t-PA expression or release, and from a plasminogen deficiency [70], there was recently a report of a total plasminogen deficiency in several patients who did not experience serious thromboembolism [71].

4.6. Inhibitors

The congenital inhibitor deficiencies usually pertain to a single inhibitor — although evidence points to a higher prevalence of combined defects than in coagulation factors (Section Coagulation Factors — whereas an acquired reduction usually includes several inhibitors. The organism contains several proteolytic systems and respective protease inhibitors; this chapter is focused on the inhibitors relevant in the hemostatic system. Congenital deficiencies of *inhibitors of the fibrinolysis system* may cause severe, hemophilia-like bleeding, but are very rare; there are no specific concentrates available. Congenital deficiencies of *coagulation inhibitors* have attracted increasing interest in the past decade, and “thrombophilia” has been coined as a new term.

A total deficiency of antithrombin III is lethal, and total deficiency of protein C is associated with the life-threatening purpura fulminans of newborns. In contrast to, e.g., hemophilia (see Section Coagulation Factors), most symptomatic patients with deficiencies of the coagulation inhibitors antithrombin III, protein C, and protein S are heterozygotes with plasma levels of around 50 % of normal, which makes the diagnostic discretion from borderline normals sometimes difficult. The affected family members show an increased tendency to mostly venous thromboembolism at a relatively young age; in antithrombin III deficiency, up to 80 % of the affected individuals may experience a thrombotic event before the age of 40 years. In contrast to hemophilia, there is no indication for prolonged substitution, with the exception of particular risk situations like major surgery and in the peripartal period in pregnancy and after delivery. Usually, it is recommended that the patients are treated by prophylactic oral anticoagulation (cumarin treatment) after the first thrombotic manifestation. A problem in patients with protein C or protein S deficiency is that these proteins are also vitamin K-dependent and their level is further lowered during cumarin treatment. Particularly in the initial phase of anticoagulation, a critical dysbalance between coagulation factors and protein C may occur; a typical clinical complication is the so-called cumarin necrosis.

In some countries, antithrombin III concentrates are licensed, which are used predominantly in acquired deficiency, as in disseminated intravascular coagulation. However, a clinical study failed to show a reduction of mortality in severe sepsis [72]. Recently, recombinant activated protein C was licensed for treatment of severe sepsis [73]. Well-controlled clinical studies are extremely difficult to perform in those severe and complex disorders.

4.7. Immunoglobulins

The most common application of immunoglobulins is the replacement of endogenous immunoglobulins in patients with immune deficiency syndromes compromising the specific immune defense. In addition, high doses of immunoglobulins may be used to overcome certain autoimmune disorders, such as idiopathic thrombocytopenic purpura (ITP) [74]. A further therapeutic segment is the application of specific immunoglobulins, which can be gained from immunized donors. A typical example is immunoglobulin against the rhesus antigen D, which is used for prophylaxis of immunization of rhesus negative mothers by rhesus positive babies, which could lead to a severe hemolytic disorder in further rhesus positive offspring.

Immunoglobulins may also be produced by recombinant techniques in order to obtain antibodies with specific pharmacological effects. Examples are antibodies against the platelet GP IIb-IIIa (see Section Thrombocytes) as a potent antiplatelet drug in high risk situations such as thrombolysis for myocardial infarction, or antibodies with specific antitumor action, which may be conjugated with antineoplastic substances.

4.8. Albumin

The use of albumin has been scrutinized following a meta-analysis of Cochrane and co-workers, who suggested an increased mortality. Though this conclusion was not substantiated, it is recommended that the indication for human albumin should focus on the use of albumin for restoration and maintenance of circulating blood volume where volume deficiency has been demonstrated and use of a colloid is appropriate [75]. Haemodynamic parameters should be monitored in patients receiving albumin due to the risk of hypervolaemia and cardiovascular overload.

[Top of Page]

5. Economic Aspects

Blood is a very precious resource from the ethical standpoint, since it is a generous gift of voluntary donors. Blood and plasma and the derivatives thereof are also of high economical value, since there are considerable expenses for the infrastructure of donation centers, donor selection and testing, storage of labile components, handling and transportation of source plasma, and industrial production of concentrates, which includes plasma fractionation, purification of proteins and virus inactivation steps. Furthermore, the quality and safety of the products should be continuously refined by ongoing research, for instance on new pathogens or their potential to cause immunological or thrombotic side effects. The treatment of patients with blood and plasma products is therefore expensive, particularly for patients who need lifelong treatment for congenital diseases such as hemophilia or immune deficiencies. This is one of the reasons, why a functional blood system and particularly supply of plasma products is so far guaranteed mainly in the developed countries; it is estimated that currently about 80 % of all hemophiliacs worldwide do not receive medically adequate treatment.

Since the financial budgets of the health care systems are limited also in economically strong nations, there is an increasing pressure to use these resources as economically as possible. The decisions in every single country are strongly influenced by medical traditions and ethical views. However, a scientific basis for estimation of the cost vs. benefit ratio of certain expensive therapeutic interventions is increasingly advocated. A typical example is the competition between plasma-derived and recombinant coagulation factors. This necessitates well-designed basic research and clinical trials, as well as solid comprehensive concepts requiring the input of scientists, clinicians, health care suppliers, regulators, politicians and, of course, the patients and the citizens, who pay for the social systems.

Despite discussions about health care budgets, it should not be forgotten, how immense the benefit of the development of transfusion is for medicine as a whole, and how dramatically the life expectancy and the quality of life of hemophiliacs improved by the introduction of replacement therapy. Thus, also in the modern medicine of increasingly sophisticated invasive procedures and the upcoming paramount of gene therapy, the medicines derived from blood and plasma should keep an important place.

1. Introduction

Blood pressure increasing agents are used to counteract acute drop of blood pressure, such as is observed in surgery, severe infectious diseases, and shock. A further field of use is persistent hypotension caused by circulatory dysregulation when standing (postural hypotension); this results in cerebral ischemia, which in turn produces clinical symptoms. Orthostatic dysregulation can also be induced by drugs, in particular by blood pressure lowering drugs (→ Antihypertensives), and by drugs acting on the central nervous system (psychotropic drugs). Hypotensive circulatory disorders may be volume-related or regulation-related. In volume-related hypotension there is an absolute deficit in blood volume, which must be compensated for by infusing blood or plasma expanders (→ Blood). Regulation-related hypotension originates either in the central nervous system or in the periphery, involving capacitance vessels (veins and venules) or resistance vessels (small arteries and arterioles) or both. In regulation-induced hypotension there is an absolute or relative deficiency in the release of norepinephrine from nerve terminals of the sympathetic nervous system in the vascular section. The release of norepinephrine is crucial to maintain vascular tone. Drug treatment, therefore, serves to supply vasoconstrictor substances, either acting like norepinephrine, i.e., sympathomimetics, or having other modes of action, i.e., ergot alkaloids, peptides, and mineralocorticoids. The mineralocorticoids also increase total blood volume. In acute hypotensive crises the drugs must be administered intravenously. For long-term hypotensive dysregulations orally effective substances are needed. The most important blood pressure increasing agents are described in this article [1].

2. Sympathomimetics

The physiological neurotransmitters of the sympathetic (adrenergic) nervous system, norepinephrine and epinephrine, and the other synthetic sympathomimetics stimulate the adrenergic α- and/or β-receptors. The stimulation of α-receptors causes the smooth muscle cells of resistance and capacitance vessels to contract; the stimulation of β_1-receptors leads to increased cardiac output, and the stimulation of β_2-receptors causes vascular smooth muscle cells to relax. Norepinephrine primarily activates α-receptors, whereas epinephrine stimulates both α- and β-receptors. Both neurotransmitters are only suitable for intravenous injection, especially for continuous i.v. infusion, because of their low bioavailability (≈ 3 %) and short half-life (≈ 2 min) [2].

Norepinephrine [*51-41-2*], (*R*)-(−)-4-(2-amino-1-hydroxyethyl)-1,2-benzenediol, (−)-norepinephrine, noradrenaline, (−)-noradrenaline, its hydrochloride [*329-56-6*], and its (*R,R*)-hydrogen tartrate [*51-40-1*] are described in more detail under → Hormones, Chap. 2.2.

Trade names(hydrochloride): Arterenol (Hoechst Marion Roussel).

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a04_229

R,R-Hydrogen tartrate: Levophed (Abbott, Breon), Levophed Bitartrate (Sanofi Winthrop), Levophed special (Abbott), Noradrenalin 1 : 1000 JENA-PHARM (Jenapharm), Noradrenalina tartrato (Monico, Salf, Sifra).

Epinephrine [*51-43-4*], (*R*)-(−)-4-[1-hydroxy-2-(methylamino)ethyl]-1,2-benzenediol, (−)-epinephrine, adrenaline, (−)-adrenaline, its hydrochloride [*55-31-2*] and its hydrogen tartrate [*51-42-3*] are described in more detail under → Hormones, Chap. 2.2.

Trade names: Adrenalina ISM 1 : 1000 (Nuovo ISM), Anahelp (Stallergènes), Anakit (Dome-Hollister-Stier), Dyspne-Inhal (Augot), EPIFRIN (Allergan), EpiPen (Dey), Primatene (Whitehall-Robins), Sus-Phrine (Forest).

Hydrochloride: Adrenalin 1 : 10000 (B. BRAUN), Ana-Kit (Bayer Allergy), Anaphylaxie-Besteck (Bencard), Fastjekt (Allergopharma), Infectokrupp Inhal (Infectopharm), Suprarenin (Hoechst Marion Roussel).

Hydrogen tartrate: Adrenalin 1 : 1000 JENA-PHARM (Jenapharm).

Dopamine [*51-61-6*], 4-(2-aminoethyl)-1,2-benzenediol, 3-hydroxytyramine, $C_8H_{11}NO_2$, M_r 153.18, is very sensitive to oxygen; its hydrochloride [*62-31-7*] melts at 247 °C.

Dopamine is the direct endogenous precursor of norepinephrine. Its cardiovascular effects are different from those of norepinephrine and epinephrine. It dilates coronary, cerebral, renal, and mesenteric arteries by interacting with dopaminergic receptors. It also activates adrenergic α- and β-receptors, which in turn causes capacitance vessels to constrict and cardiac output to increase. With this combined effect dopamine is well suited for shock treatment: it increases blood pressure, and at the same time renal and mesenteric blood flow is augmented. In terms of pharmacokinetics, dopamine is similar to norepinephrine and epinephrine and must be administered by continuous intravenous infusion [3].

Dopamine is synthesized from veratrole by chloromethylation to form veratryl chloride, followed by cyanation, catalytic hydrogenation, and demethylation.

For further methods of synthesis, see [9].

(see a: [4]; b: [5]; c: [6]; d: [7]; e: [8])

Trade names(hydrochloride): Dopamin Fresenius (Fresenius-Klinik), Dopamin-ratiopharm (ratiopharm), Dopamin Solvay (Solvay Arzneimittel), Dopamine Pierre Fabre (Pierre Fabre Cardio Vasculaire), Dopamine Lucien (Therabel Lucien Pharma), Dopamine Nativelle (Procter & Gamble), Revivan (Astra).

Norfenefrine [*536-21-0*], α-(aminomethyl)-3-hydroxybenzenemethanol, $C_8H_{11}NO_2$, M_r 153.18, is closely related to norepinephrine; its hydrochloride [*4779-94-6*] melts at 159 – 160 °C.

The bioavailability of norfenefrine is only slightly greater (≈ 5 %) than that of norepinephrine because the major portion is metabolized in the intestinal wall and the liver (extensive first-pass effect). When administered orally the compound is only effective at high dose levels [10].

Norfenefrine can be synthesized from *m*-hydroxyacetophenone as shown in the following scheme [11]:

Norfenefrine is also obtained from *m*-hydroxyacetophenone by nitrosation to form *m*-hydroxy-(hydroxyimino)acetophenone and subsequent catalytic hydrogenation [12]:

For a further method of synthesis, see [13]. Trade names(hydrochloride): Coritat (Green Cross), Energona (Maurer), Norfenefrin "Ziethen" (Ziethen), Norfenefrin retard forte-ratiopharm (ratiopharm), Novadral (Goedecke), Zondel (Grelan).

Midodrine [*42794-76-3*], 2-amino-*N*-[2-(2,5-dimethoxyphenyl)-2-hydroxyethyl]acetamide, $C_{12}H_{18}N_2O_4$, M_r 254.28, and its hydrochloride [*3092-17-9*], *mp* 202 – 204 °C, act on resistance and capacitance vessels by stimulating α-receptors. Midodrine is a prodrug from which the active major metabolite ST 1059, α-(aminomethyl)-2,5-dimethoxybenzenemethanol, is released by enzymatic cleavage of glycine. According to animal experiments the enteral efficacy of midodrine is better than that of the sympathomimetics already described. However, no data on the bioavailability and half-life of this relatively new compound have been published [14]. Synthesis [15]:

For further routes to midodrine, see [16]. Trade names(hydrochloride): Gutron (Guidotti, Nycomed), Metligine (Taisho), ProAmatine (Roberts).

Etilefrine [*709-55-7*], α-[(ethylamino)methyl]-3-hydroxybenzenemethanol, $C_{10}H_{15}NO_2$, M_r 181.23, *mp* 147 – 148 °C, and its hydrochloride [*943-17-9*], *mp* 121 °C, act both on α-receptors and on β-receptors. This not only increases the tone of resistance and capacitance vessels but also improves the cardiac output. The bioavailability of the compound is 55 % when administered in aqueous solution, 35 % when administered as an instant-release tablet, and 17 % as a slow-release tablet. Bioavailability increases to 61 % when 2 mg of dihydroergotamine (see page 4) is added to a slow-release tablet [17].

Etilefrine can be synthesized using *m*-acetoxy-ω-bromoacetophenone as the starting material:

(see a: [18]; b: [19]; c: [20], [21])

For an alternate route to etilefrine, see [20].

Trade names(hydrochloride): Adrenam (NAM Neukönigsförder), Bioflutin-N (Südmedica), Cardanat (Temmler Pharma), Cardialgine (MIP Pharma), Circupon RR (gegepharm), Circuvit E (Pharma Wernigerode), Confidol (Medopharm), Effortil (Boehringer Ingelheim), etil 5 von ct (ct-Arzneimittel), ETI-PUREN (Isis-Puren), Kreislauf Katovit (Boehringer Ingelheim), Thomasin (Apogepha).

Hydrochloride in combination with dihydroergotamine methanesulfonate see page 4.

Ameziniummetilsulfate [*30578-37-1*], 4-amino-6-methoxy-1-phenylpyridazinium methyl sulfate, amezinium, $C_{12}H_{15}N_3O_5S$, M_r 313.33, *mp* 176 °C (decomp.), also acts via adrenergic α- and β-receptors. Its chemical structure differs from that of other sympathomimetics. At the adrenergic neurons the drug causes specific, reversible inhibition of monoamine oxidase, inhibition of norepinephrine re-uptake, and a slight increase in norepinephrine release. Therefore, the agent is only effective in vessels innervated by adrenergic nerves, thereby enhancing sympathetic activity. Unlike other indirectly acting sympathomimetic drugs, ameziniummetilsulfate does not deplete the norepinephrine stores in sympathetic nerve terminals. Its bioavailability is ca. 60 %, the terminal half-life is 9 – 17 h [22].

The substance is prepared by first treating 4,5-dichloro-2-phenyl-3(2*H*)-pyridazinone [23] with ammonia to give mainly 5-amino-4-chloro-2-phenyl-3(2*H*)-pyridazinone and some 4-amino-5-chloro-2-phenyl-3(2*H*)-pyridazinone [23].

After removal of the 4-amino-5-chloro derivative by extraction with chloroform [24], [25], the 5-amino-4-chloro compound is dehalogenated with hydrogen over Raney nickel [23], [25] or with sodium borohydride in the presence of palladium on charcoal [26]. Subsequent reaction with dimethyl sulfate leads to ameziniummetilsulfate [25], [27].

Trade names: Regulton (Knoll Deutschland), Risumic (Dainippon), Supratonin (Grünenthal).

3. Substances Having Other Modes of Action

3.1. Ergot Alkaloids

Dihydroergotamine [*511-12-6*], (5′α,10α)-9,10-dihydro-12′-hydroxy-2′-methyl-5′-(phenylmethyl)ergotaman-3′,6′,18-trione, 9,10-dihydroergotamine, is treated in more detail under → Alkaloids, Chap. 11.3.2.; the methanesulfonate [*6190-39-2*] melts at 230 – 235 °C (decomp.).

Dihydroergotamine acts on adrenergic α-receptors and serotonin receptors of capacitance vessels and increases their tone. In this way blood supply to the heart and stroke volume are improved. As a consequence, blood pressure is increased. To a great extent dihydroergotamine acts selectively on capacitance vessels, whereas an increase in the tone of resistance vessels has only been demonstrated in denervated vessel preparations. The bioavailability of the drug is only about 1 %. However, its effect on venous tone has been clearly demonstrated in animals and humans after oral administration and can be explained by an accumulation of the agent in the smooth muscle cells of the vessels. Therefore, its effect is largely independent of plasma levels [28].

Dihydroergotamine can be obtained by hydrogenating ergotamine (→ Alkaloids) in the presence of a palladium catalyst [29].

Trade names(methanesulfonate): Agit depot sanol (Sanol), Angionorm (Farmasan), clavigrenin (Hormosan), DET MS (FUISZ PHARMA), D.H.E. 45 (Novartis), DHE-PUREN (Isis-Puren), DHE-ratiopharm (ratiopharm), Dihydergot (Novartis Pharma), Dihytamin (Arzneimittelwerk Dresden, Temmler Pharma), Diidergot (Sandoz), Ergomimet (Klinge), Ergont (Desitin), ergotam von ct (ct-Arzneimittel), Ikaran (Pierre Fabre, Formenti), Migranal (Novartis), Seglor (Sanofi Winthrop, Synthelabo), Verladyn (Verla).

Methanesulfonate in combination with etilefrine hydrochloride: Effortil plus (Boehringer Ingelheim), Ergolefrin (gegepharm), Agit plus sanol (Sanol), Dihydergot plus (Novartis Pharma), Ergomimet plus (Klinge).

3.2. Mineralocorticoids

Therapy of postural hypotension by mineralocorticoids (renin – angiotensin – aldosterone mechanism) is based on sodium and water retention in the body. This increases the blood volume and makes the vessels more sensitive to vasoconstrictive agents, resulting in augmented tone of resistance and capacitance vessels. Fludrocortisone is normally used; it has a bioavailability of 100 %. On prolonged administration, fludrocortisone inhibits the production of renin, angiotensin, and aldosterone and causes atrophy of aldosterone-producing cells in the adrenal gland. Therefore, fludrocortisone is only used in the treatment of postural circulatory dysregulation where other drugs have failed. In any case treatment must be short [30].

Fludrocortisone [*127-31-1*], (11β)-9-fluoro-11,17,21-trihydroxypregn-4-ene-3,20-dione, 9α-fluorohydrocortisone, 9α-fluorocortisol, $C_{21}H_{29}FO_5$, M_r 380.46, *mp* 260 – 262 °C (decomp.), $[\alpha]_D^{23}$ + 139° (c = 0.55, 95 % ethanol); 21-acetate [*514-36-3*], $C_{23}H_{31}FO_6$, M_r 422.48, crystalline substance, several polymorphic forms, *mp* 233 – 234 °C (occasionally melting at 205 – 208 °C, resolidification and subsequent melting at 226 – 228 °C, $[\alpha]_D^{23}$ + 123° (c = 0.64, chloroform); for the synthesis of the 21-acetate, see [31–33] and for its conversion to fludrocortisone, see [31], [34]; see [35] for a broad description of the 21-acetate and [36] for a process giving dense granular prisms of the 21-acetate.

Trade names: Astonin H (Merck).

21-Acetate: Florinef (Bristol-Myers Squibb), Florinef Acetate (Apothecon), Fludrocortison (Bristol-Myers Squibb).

1. Introduction

In spite of the fact that many drugs are now available for the treatment of hypertension, new drugs are being introduced every year. The existence of a lucrative and still expanding market as well as the medical need for effective antihypertensive drugs with minimal side effects stimulate continuous research activity in this field.

The available antihypertensive drugs can be classified on the basis of their mechanism of action as follows: (1) diuretics, (2) inhibitors of angiotensin converting enzyme (ACE), (3) drugs which interfere with the sympathetic nervous system, and (4) vascular smooth muscle relaxants. This article describes the major representatives of each of the above classes of antihypertensive drugs.

2. Diuretics

The chemistry, pharmacology, and clinical use of diuretics in hypertension and edema are discussed in [1], also → Diuretics. The rapid expansion of the diuretic field occurred after the introduction of acetazolamide [2] and chlorothiazide [3], [4]. The discovery of the effectiveness of chlorothiazide in the therapy of hypertension [5] greatly expanded the market for diuretics and led to the synthesis of many chemically related compounds. Since hypokalemia is one of the major side effects of chlorothiazide and related thiazides, attempts were made to develop diuretics with K^+-retaining or isokalemic properties. Aldosterone antagonists, such as spironolactone or other K^+ retaining diuretics, e.g., amiloride [6] or triamterene [7] were shown to produce diuresis while reducing excretion of potassium. Combinations of thiazides with potassium retaining diuretics (e.g., Moduretic or Dyazide) have diuretic effects and lower arterial pressure without any change in the excretion of potassium. These combinations are widely used in general practice.

The *mechanism* of antihypertensive action of diuretics is still a subject of controversy, although numerous studies suggested that the natriuretic action of diuretics is primarily responsible for their antihypertensive effect. The kidneys of hypertensive animals or humans can excrete salt in normal amounts but only at elevated arterial pressure levels and diuretics increase the excretion of salt independent of blood pressure level [8]. Also the increase in sodium in the vascular smooth muscle cell was correlated with the increase in the intracellular calcium, and therefore, with the vasoconstrictor tone leading to the elevation of arterial pressure [9], [10]. The natriuretic effect of diuretics tends to prevent excessive accumulation of sodium.

2.1. Sulfonamide Diuretics

The first sulfonamide shown to have diuretic activity in humans was sulfanilamide [*63-74-1*] [11]. Subsequent attempts to improve the activity and to reduce the side effects of sulfanilamide led to the development of acetazolamide [*59-66-5*] [12], which can be considered the prototype of sulfonamide diuretics. Its continuous use led to metabolic acidosis and to the development of tolerance to its diuretic effect. The search for a better diuretic led to the development of chlorothiazide [*58-94-6*] [13]. The diuretic activity of chlorothiazide, unlike that of acetazolamide, is not determined by its carbonic anhydrase inhibitory activity. At therapeutic doses, chlorothiazide increases the excretion of chloride rather than that of hydrogen carbonate. By repeated administration chlorothiazide produces effective diuresis without metabolic acidosis.

Extensive structure – activity relationship studies led subsequently to the development of chemically and pharmacologically related thiazide diuretics which differed from chlorothiazide either in the relative potency or in the duration of action. The most commonly used thiazide diuretic is hydrochlorothiazide [14], which is ca. 10 times more potent than chlorothiazide. The most potent thiazide among marketed drugs is cyclopenthiazide [15], while methylclothiazide [16] and polythiazide [17] have exceptionally long durations of action. Their longer duration of action is due to higher lipid solubility (and therefore greater reabsorption of the drug in the proximal tubules) and higher protein binding. Other clinically important sulfonamide diuretics include mefruside [18], [19], indapamide [20], and chlorthalidone [21].

A significant advance in diuretic therapy was the introduction of furosemide [12], which has much higher ceiling natriuretic and chloruretic effects than thiazide diuretics. The high ceiling effect of furosemide is determined by the site of its tubular action: furosemide inhibits chloride and sodium reabsorption in the ascending limb of Henle's loop ("loop" diuretic). Furosemide is widely used clinically, although in hypertension it is not more effective than thiazide diuretics. An attempt to find a "loop" diuretic with a long duration of action led to the development of muzolimine [21], which is not yet available on the United States market.

2.1.1. Hydrochlorothiazide

Hydrochlorothiazide [*58-93-5*], 6-chloro-3,4-dihydro-2*H*-1, 2, 4-benzothiadiazine-7-sulfonamide 1,1-dioxide, $C_7H_8ClN_3O_4S_2$, M_r 297.72, *mp* 273 – 275 °C, is insoluble in water, soluble in NaOH, ethanol, and acetone. Hydrochlorothiazide is widely used in the treatment of hypertension or edema.

Trade names: HydroDiuril, Esidrix.

Like other benzothiadiazine-type diuretics (or thiazides), hydrochlorothiazide increases the excretion of sodium and chloride independent of acid – base balance. Hydrochlorothiazide also increases the excretion of potassium. The resulting hypokalemia represents its major *side effect.* Other side effects include hyperuricemia, hyperglycemia, and hyperlipoproteinemia. The relative diuretic potency of hydrochlorothiazide is ca. 10 times higher than that of chlorothiazide [14]. The efficacy (ceiling effect) is similar to that of other thiazide diuretics and is considerably lower than that of furosemide. Daily clinical doses range from 25 to 200 mg and are given with potassium supplements or in combination with potassium-retaining diuretics to prevent hypokalemia.

2.1.2. Chlorthalidone

Chlorthalidone [*77-36-1*], 2-chloro-5-(1-hydroxy-3-oxo-1-isoindolinyl)benzenesulfonamide, $C_{14}H_{11}ClN_2O_4S$, M_r 338.78, *mp* 224 – 226 °C, is slightly soluble in water (12 mg/100 mL), more soluble in diluted NaOH or warm ethanol.

Trade name: Hygroton.

Chlorthalidone is pharmacologically similar to thiazide diuretics but is substantially longer acting than hydrochlorothiazide [21]. The duration of action is determined by its elimination half-life ($t_{1/2}$) of 49 h in humans. Because of longer duration of action, chlorthalidone can be given every 72 h. Chlorthalidone is widely used in the treatment of hypertension: it can be used alone or in combination with methyldopa or β-adrenoceptor antagonists. *Side effects* are also similar to those of thiazides and include hypokalemia, hyperuricemia, hyperglycemia, and hyperlipoproteinemia (elevation of low-density lipoproteins). Clinical doses range from 25 to 400 mg.

2.1.3. Furosemide

Furosemide [*54-31-9*], 5-(aminosulfonyl)-4-chloro-2-[(2-furanylmethyl)amino]benzoic acid, 4-chloro-*N*-furfuryl-5-sulfamoylanthranilic acid, $C_{12}H_{11}ClN_2O_5S$, M_r 330.77, *mp* 206 °C, is only slightly soluble in water, soluble in methanol, acetone, and dilute NaOH.

Trade name: Lasix.

The major site of action of furosemide is in the ascending limb of Henle's loop, proximal to the thiazide diuretics. Like thiazides, furosemide increases the excretion of sodium, chloride, and potassium, but its efficacy (ceiling effect) is much higher than that of thiazides and similar diuretics [12]. The duration of diuretic action of furosemide is short and is correlated with its elimination half-life (0.85 h). Independent of its diuretic action, furosemide, by i.v. administration, tends to increase venous capacitance and to reduce left ventricular end diastolic pressure. In spite of its greater diuretic efficacy, furosemide is not more effective than thiazide diuretics in the treatment of hypertension. *Side effects* of furosemide include those of thiazide diuretics: hypokalemia, hyperglycemia, hyperuricemia, and hyperlipoproteinemia. In addition, furosemide tends to produce metabolic alkalosis and ototoxicity, which is typical for "loop" diuretics. Daily clinical doses of furosemide range from 20 to 200 mg.

2.1.4. Mefruside

Mefruside [*7195-27-9*], 4-chloro-N^1-methyl-N^1-[(tetrahydro-2-methyl-2-furanyl)methyl]-1,3-benzenedisulfonamide, 4-chloro-N^1-methyl-N^1-(tetrahydro-2-methylfurfuryl)-*m*-benzenedisulfonamide, $C_{13}H_{19}ClN_2O_5S_2$, M_r 382.90, *mp* 149 – 150 °C (DL-crystals), 146 °C (D-form). The D-form is more active as a diuretic than the L-form.

Trade name: Baycaron.

The primary site of action of mefruside is the cortical diluting segment; duration of action is 20 to 24 h. Mefruside has carbonic anhydrase inhibitory activity but is less potent than acetazolamide [18], [19]. One of its metabolites, oxomefruside, also has diuretic activity. *Side effects* of mefruside are similar to those of thiazide diuretics, in that it produces hyperuricemia and hypokalemia. Daily clinical doses range from 25 to 200 mg. In hypertension, mefruside is effective at 25 – 50 mg/d or every other day.

2.1.5. Indapamide

Indapamide [*26807-65-8*], 3-(aminosulfonyl)-4-chloro-*N*-(2,3-dihydro-2-methyl-1*H*-indol-1-yl)benzamide, 4-chloro-*N*-(2-methyl-1-indolinyl)-3-sulfamoylbenzamide, $C_{16}H_{16}ClN_3O_3S$, M_r 365.84, *mp* 160 – 162 °C, pK_a 8.3, is lipid soluble.

Trade names: Fludex, Ipamox, Natrilix.

The site of diuretic action of indapamide is similar to that of thiazide diuretics: the proximal part of distal tubules. Its duration of diuretic action can exceed 24 h. Indapamidediffers from thiazide diuretics in having additional direct smooth muscle relaxant effect and hypotensive effect at doses below those required to produce diuresis [20].

Side effects of indapamide include hypokalemia, hyperuricemia, and metabolic alkalosis, and are usually observed at doses higher than required for satisfactory control of arterial pressure in hypertensive patients (5 mg/d and higher). The safe and effective clinical dose is 2.5 mg/d.

2.2. K^+-Retaining Diuretics

The development of K^+-retaining (or sparing) diuretics was stimulated by the fact that K^+ loss and consequent hypokalemia represent the major side effect of sulfonamide diuretics. It was considered possible to develop K^+-retaining diuretics because aldosterone was known to retain sodium while increasing the excretion of potassium. The search for aldosterone inhibitors led to the development of spironolactone [*52-01-7*] [22], which is still used clinically. The activity of spironolactone is determined by its ability to compete with aldosterone at its receptor sites. It is inactive in the absence of aldosterone but has diuretic, natriuretic, and K^+ retaining effects in its presence. The pharmacological effects of spironolactone are to a great extent due to its active metabolite, canrenone, which is formed within 3 min after administration of spironolactone and has a half-life of ca. 12 h.

The clinical use of spironolactone is severely limited by *side effects,* including hyperkalemia, gynecomastia, impotence, and menstrual cycle abnormalities. In rats chronic spironolactone treatment was tumorigenic, and therefore, its use is restricted. Because of these side effects and the high cost of spironolactone, the search for nonsteroidal aldosterone inhibitors continued and led to the development of K^+-retaining diuretics that increase sodium excretion without inhibiting aldosterone.

Two major K^+-retaining diuretics which do not inhibit aldosterone are amiloride and triamterene.

2.2.1. Amiloride

Amiloride [*2609-46-3*], 3,5-diamino-*N*-(aminoiminomethyl)-6-chloropyrazinecarboxamide, *N*-amidino-3,5-diamino-6-chloropyrazinecarboxamide, $C_6H_8ClN_7O$, M_r 229.65, *mp* 293.5 °C, is soluble in water. It is widely used in combination with hydrochlorothiazide (Moduretic).

Trade names: Colectril and Midamor.

The site of action of amiloride is in the distal portion of distal tubules and in the collecting duct, where amiloride inhibits sodium reabsorption and potassium secretion [6]. It is thought to block the Na^+ channel and the Na^+/H^+ exchange pump. In addition to the renal tubules, amiloride blocks Na^+ channels in various epithelial membranes, including the salivary ducts. In hypertension, if used alone, amiloride is not as effective as hydrochlorothiazide. The major *side effect* of amiloride is hyperkalemia. Other side effects include nausea, anorexia, and abdominal pain.

The clinical dose range of amiloride is 5 – 20 mg/d. Potassium supplements are contraindicated with amiloride; other K^+-retaining diuretics should not be combined with amiloride.

2.2.2. Triamterene

Triamterene [*396-01-0*], 6-phenyl-2,4,7-pteridinetriamine, 2,4,7-triamino-6-phenylpteridine, $C_{12}H_{11}N_7$, M_r 253.26, *mp* 316 °C, is insoluble in water or chloroform and only slightly soluble in alcohol.

Trade names: Dyrenium; Dyazide (combination with hydrochlorothiazide).

Triamterene increases urinary excretion of sodium and chloride and decreases excretion of potassium and hydrogen ions. The primary site of triamterene action is in the distal tubules [7]. The biochemical effects of triamterene are not well-known, although triamterene is capable of forming "false" nucleotides.

The principal use of triamterene is in combination with hydrochlorothiazide. The natriuretic effects of both diuretics are additive, but the kaliuretic effect of hydrochlorothiazide is antagonized by triamterene.

The major *side effect* of triamterene alone is hyperkalemia. Nausea, leg cramps, and dizziness have also been described. The initial clinical dose is 100 mg twice daily. Dyazide capsules contain 50 mg of triamterene and 25 mg of hydrochlorothiazide and are given 1 – 4 times daily.

2.3. Other Diuretics

In addition to sulfonamides and pyrazines, diuretic activity has been discovered among many other chemical classes of drugs. Among them are aryloxyacetic acids, 2-aminomethylphenols, and various heterocyclic compounds. Because all diuretics cannot be covered in this article, compounds that are important therapeutically as well as historically have been selected. The three diuretics discussed (ethacrynic acid, indacrinone, and muzolimine) differ from sulfonamides and pyrazines in their pharmacological profiles and represent three different chemical classes.

2.3.1. Ethacrynic Acid

Ethacrynic acid [*58-54-8*], [2,3-dichloro-4-(2-methylene-1-oxybutyl)phenoxy]acetic acid, $C_{13}H_{12}Cl_2O_4$, M_r 303.14, *mp* 121 – 125 °C, is only slightly soluble in water but very soluble in alcohol (1 g/1.6 mL).

The efficacy (ceiling effect) of ethacrynic acid is similar to that of furosemide and considerably higher than that of hydrochlorothiazide. Ethacrynic acid increases the excretion of sodium and chloride. It also slightly increases the excretion of potassium. The major site of action is the ascending limb of Henle's loop [13]. The biochemical mechanism of action is not known precisely, although at high concentrations ethacrynic acid inhibits renal Na^+-K^+ dependent ATPase and oxygen consumption in medullary tubules. Ethacrynic acid reacts with thiols in the body fluids and forms adducts which are likely to represent the active forms of this

drug. The *side effects* of ethacrynic acid include abdominal discomfort, nausea, hyperuricemia, neutropenia, thrombocytopenia, ototoxicity, and metabolic alkalosis. The usual clinical doses are 50 mg twice a day; the maximal daily dose is 400 mg.

2.3.2. Indacrinone

Indacrinone [*57296-63-6*], [(6,7-dichloro-2,3-dihydro-2-methyl-1-oxo-2-phenyl-1*H*-inden-5-yl)oxy]acetic acid, M_r 365.19. A 9 : 1 ratio of (+)- to (−)-indacrinone enantiomers was studied as MK-286 and found to be isouricemic during chronic use. The (+)-enantiomer is uricosuric, whereas the (−)-enantiomer retains uric acid. The racemic mixture was tested as MK-196 [23–25].

Indacrinone and its enantiomers lower arterial pressure in hypertensive animals and in humans, inhibit sodium and chloride reabsorption in the ascending limb of Henle's loop, and increase excretion of potassium. Hypokalemia can be antagonized by amiloride. The site of action of enantiomers in the renal tubules appears to differ. The (−)-enantiomer has its primary action in the medullary portion of the ascending limb, while the (+)-enantiomer has its primary action in the cortical diluting segment. The saluretic efficacy of indacrinone is similar to or greater than that of furosemide, while the duration of action is longer. *Side effects* of indacrinone in humans include headache, lethargy, weakness, dry mouth, and slight, but transient elevations in SGOT and/or SGPT. The clinical doses of the (−)-enantiomer ranged from 10 to 40 mg, while the (+)-enantiomer was given at doses from 10 to 400 mg.

2.3.3. Muzolimine

Muzolimine [*55294-15-0*], 5-amino-2-[1-(3,4-dichlorophenyl)-ethyl]-2,4-dihydro-3*H*-pyrazol-3-one, $C_{11}H_{11}Cl_2N_3O$, M_r 272.13, *mp* 127–129 °C, is insoluble in water, but is soluble in ethanol, polyethylene glycol, or dimethyl sulfoxide. It is highly lipophilic, with a pK_a value of 9.3 and a partition coefficient in octanol/water of 2.29.

Trade name: Edrul.

The site of diuretic action of muzolimine is the ascending limb of Henle's loop. Unlike other loop diuretics muzolimine does not act at the luminal site. It appears to inhibit sodium and chloride transport at the peritubular site of the cell membrane. Muzolimine exhibits a high-efficacy (ceiling) effect similar to that of furosemide, but has a considerably longer duration of action. The duration of antihypertensive action of muzolimine at a single dose exceeds 24 h [26], [27].

Clinical doses of muzolimine range from 10 to 480 mg; good therapeutic results were obtained with doses of 30 mg/d in most patients. Muzolimine is particularly useful in the treatment of edema associated with renal failure.

3. Inhibitors of Angiotensin Converting Enzyme

The renin–angiotensin system is involved in the control of blood pressure in normotensive and hypertensive states. The conversion of angiotensinogen to angiotensin II involves a two-step sequence:

Pharmacological approaches for interference with the renin – angiotensin system have focused on renin inhibitors, angiotensin converting enzyme (ACE) inhibitors, and angiotensin II receptor antagonists [28]. Captopril was the first orally effective ACE inhibitor approved for use in mild-to-moderate hypertension. Enalapril was developed later as a nonsulfhydryl-containing inhibitor.

3.1. Captopril

Captopril [*62571-86-2*], 1-(3-mercapto-2-methyl-1-oxopropyl)-L-proline, $C_9H_{15}NO_3S$, M_r 217.28, *mp* 87 – 88 °C, is soluble in water, alcohol, and chloroform;

Trade name: Capoten.

The rationale and design of the angiotensin converting enzyme (ACE) inhibitors have been described [29], [30]. The effectiveness of captopril on ACE was shown by its ability to inhibit the rise in blood pressure induced by angiotensin I, while leaving unchanged the responses to angiotensin II [31].

It has been postulated that the antihypertensive mechanism may include not only inhibition of plasma ACE activity, but also inhibition of local tissue ACE, especially in the vascular smooth muscle [32–35]. In addition, a number of alternative mechanisms could explain the efficacy of ACE inhibitors in nonrenin-dependent hypertension [36]. The alternatives include (1) interference with α-adrenergic vasoconstriction [37–42]; (2) a central inhibition of sympathetic nervous outflow [35], [43]; (3) elevation in bradykinin or prostaglandins, due to the similarity of kininase II and ACE [31], [32], [44]; and (4) alteration in the permeability of vascular smooth muscle to sodium ions [45].

Clinically, the antihypertensive actions of captopril are associated with a reduction in total peripheral resistance and a slight to moderate increase in cardiac output [46], [47]. In malignant hypertensive patients captopril was very effective during acute and long-term treatment [48].

The hypotensive responses are not usually accompanied by a reflex increase in heart rate. Captopril facilitates the reflex slowing of heart rate in some manner [38]. This could involve the removal of facilitatory effects of angiotensin II on sympathetic nervous transmission to the heart or a central inhibitory effect of angiotensin II on cardiac vagal tone [49]. Further studies have also indicated that captopril possesses cardioprotective properties [50].

Captopril decreases renal vascular resistance, and increases sodium and water excretion [51], [52].

Renin levels are increased and aldosterone levels are reduced by captopril. A certain number of patients with essential hypertension exhibit a subnormal aldosterone secretory response to angiotensin II challenge [53]. The abnormal responders also exhibit higher baseline plasma angiotensin II and lower levels of aldosterone. Captopril treatment for 72 h removed the difference in baseline values and partially corrected the abnormal aldosterone response to angiotensin II.

The absorption of captopril in humans is rapid and extensive; 75 % of the radioactivity after a single oral dose of ^{14}C-captopril was recovered in the urine within 48 h. The metabolites of captopril include disulfides and endogenous sulfhydryl compounds, e.g., cysteine.

The *side effects* of captopril include proteinuria, maculopapular rash, itch, disturbance of taste, and occasional leukopenia [54].

3.2. Enalapril

Enalapril [*75847-73-3*], 1-[*N*-[1-(ethoxycarbonyl)-3-phenylpropyl]-L-alanyl]-L-proline, $C_{20}H_{28}N_2O_5$, M_r 376.45, *mp* 143 – 144.5 °C, is a white to off-white crystalline powder, soluble in methanol and slightly soluble in water. Unlike captopril, enalapril does not contain the sulfhydryl moiety which has been implicated in some adverse side effects, such as rash and loss of taste.

Enalapril is readily absorbed by oral administration while the active diacid form is poorly absorbed. Deesterification of the prodrug takes place primarily in the liver [55]. Enalapril is about 17-fold more potent than captopril for inhibition of hog plasma ACE. In both rats and dogs, enalapril inhibits the pressor responses to angiotensin I for approximately 6 h. Although the onset of action is somewhat slower, the potency of enalapril in vivo is about 4 – 8 fold greater than that of captopril in the same species [56].

Similar to captopril, the antihypertensive action of enalapril is most pronounced in high-renin forms of hypertension and enalapril also exhibits antihypertensive activity in low-renin models [57].

In clinical studies, enalapril effectively lowers arterial pressure when given as sole therapy or in combination with diuretics [58–60]. Similar to preclinical studies, the onset of inhibition of ACE in humans is slower than with captopril. This finding has been attributed to the time needed for the deesterification reaction [61].

Reflex tachycardia is seldom observed with enalapril [62], [63]. Cardiac function is well-maintained [62], [64] and, in one group of hypertensive patients, the left ventricular mass was reduced during therapy [62].

With regard to renal function, enalapril increases sodium excretion, glomerular filtration rate, and renal blood flow in sodium-restricted dogs [55]. In spontaneously hypertensive rats (SHR), antihypertensive doses of enalapril do not cause sodium and water retention upon chronic administration [65]. Renal vasodilatation and natriuresis have been observed in hypertensive patients treated with enalapril [62], [63].

Hormonal responses during acute and chronic (3 months) enalapril treatment consist of decreased angiotensin II and aldosterone levels and a rise in plasma renin activity. In addition, bradykinin and PGE_2 were unchanged by a single dose of enalapril [63], [66]. Epinephrine levels were consistently decreased by enalapril, whereas, in hypertensive patients during chronic therapy with enalapril, plasma norepinephrine was reduced insignificantly [62]. In normotensive subjects, the direction of change in norepinephrine levels was dependent on the sodium intake [66], [67].

The mechanism of action of enalapril remains to be fully elucidated. The dominant mechanism most certainly involves the renin–angiotensin system; however, additional mechanisms must also be considered.

The major toxicological findings in dogs were renal functional changes, and renal tubular degeneration. Toxic actions of enalapril are exacerbated by coadministration of hydrochlorothiazide and attenuated by saline supplements [55]. In humans the major *side effects* include rash, angioedema, proteinuria, and renal insufficiency [54].

4. Inhibitors of the Sympathetic Nervous System

4.1. Drugs with Primarily Central Actions

Some of the widely used antihypertensive drugs are thought to lower arterial pressure by centrally induced blockade of sympathetic tone and consequent reduction of peripheral vascular resistance. The central control of the sympathetic nervous system is mediated by various neurotransmitters, including norepinephrine, and by drugs which enhance norepinephrine release or stimulate postsynaptic α-adrenoceptors involved in the regulation of sympathetic tone. The 5HT agonists, dopaminergic, or GABA ergic drugs, were also shown or are assumed to control hypertension by a central action. It is presently not clear whether their effects are mediated through central inhibition of the sympathetic nervous system or by other central mechanisms.

The major goal in the development of new centrally acting drugs is to achieve a high degree of selectivity for blood pressure control, which would lead to antihypertensive action without sedative, skeletal muscle relaxant, or emetic side effects. For further details on the central control of arterial pressure by drugs see reviews [68], [69].

4.1.1. Methyldopa

The antihypertensive activity of methyldopa [*555-30-6*], 3-hydroxy-α-methyl-L-tyrosine, $C_{10}H_{13}NO_4$, M_r 211.21, was first attributed to the inhibition of aromatic amino acid decarboxylase [70] and later to a formation of a "false transmitter" [71], [72]. It is postulated that α-methylnorepinephrine, a methyldopa metabolite, lowers arterial pressure by stimulating central adrenoceptors, which causes a reduction in sympathetic nervous outflow [73], [74].

The antihypertensive effect of methyldopa in humans is associated with a reduction in the peripheral vascular resistance and in the plasma renin activity [74–76]. Methyldopa increases coronary and cerebral blood flow [77], [78].

The oral absorption of methyldopa in humans was reported to vary from 26 to 74 % [79]. The peak plasma levels of methyldopa are observed 3 – 6 h after oral dose. The major urinary metabolites of methyldopa are methyldopa-*o*-sulfate and 3-methoxymethyldopa. About 80 to 90 % of the oral dose of methyldopa is eliminated within 48 h after treatment [80].

The initial dose of methyldopa in mild hypertension is 250 mg t.i.d. (3 times/d), whereas in severe hypertension methyldopa is used at doses up to 500 mg q.i.d. (4 times/d). The clinical advantages of methyldopa include its effectiveness in controlling hypertension, many years of clinical experience, and favorable hemodynamic effects, including maintenance of renal circulation and decrease in plasma renin activity. *Side effects* of methyldopa include sedation, positive direct Coomb's test, hepatotoxicity, and allergic reactions.

4.1.2. Clonidine

Clonidine [*4205-90-7*], 2-(2,6-dichloroanilino)-2-imidazoline, $C_9H_9Cl_2N_3$, M_r 230.10, *mp* ca. 300 °C, pK_a 8.2, is easily soluble in water (1 g/13 mL) and ethanol (1 g/25 mL).

Trade names: Catapres, Catapressan.

Clonidine is an α-adrenoceptor stimulant, which stimulates preferentially α_2-adrenoceptors [81], [82]. The stimulation of central α-adrenoceptors by clonidine leads to inhibition of central sympathetic tone, resulting in a lowering of arterial pressure and of heart rate [83–87].

Clonidine has many other pharmacological effects. The most prominent central effect of clonidine is sedation. Clonidine decreases spontaneous motor activity and produces ataxia and catatonia as well as signs of increased peripheral sympathetic activity in animals, i.e., piloerection and exophthalmus [88]. Clonidine has antinociceptive activity in mice [89] and is effective in the management of withdrawal reaction in opiate addicts [90]. Intraocular pressure is decreased by clonidine [91]. Clonidine reduces salivary secretion and has a biphasic effect on gastric secretion: inhibition at lower and stimulation at higher doses [88], [92]. In rats and dogs clonidine has a diuretic effect which appears to be mediated by inhibition of ADH release [93].

Clonidine is almost completely absorbed by oral administration; its bioavailability in humans is ca. 75 % and the drug has no extensive first-pass metabolism [94]. In humans ca. 50 % of clonidine is excreted unchanged. The major metabolites of clonidine are *p*-hydroxyclonidine and dichlorophenylguanidine [84].

The major *undesirable effect* of clonidine is the withdrawal reaction, which consists of a sudden rise in arterial pressure, nervousness, agitation, and an increase in heart rate [95], [96]. Other side effects include dry mouth and sedation.

The recommended starting dose of clonidine is 0.1 mg/d, but it should not exceed a total daily dose of 1 mg. The pharmacology of clonidine is reviewed extensively elsewhere [84].

4.1.3. Guanfacine

Guanfacine [*29110-47-2*], *N*-amidino-2-(2,6-dichlorophenyl)acetamide, $C_9H_9Cl_2N_3O$, M_r

246.08, *mp* 214 – 218 °C, is water soluble with a pK_a of 7.1. Guanfacine is one of the most potent members of a class of antihypertensive phenylacylguanidines [97].

Trade names: Estulic, Estuline.

Guanfacine is similar to clonidine in that the mechanism of antihypertensive action is attributed largely to stimulation of central adrenoceptors [98], [99]. Guanfacine is claimed to differ from clonidine in having less depressant effect on the central nervous system (CNS) and possibly may act at a different site within the CNS [100], [101]. Like clonidine, guanfacine exhibits a peripheral vasoconstrictor effect that is mediated most likely by stimulation of α_2-adrenoceptors. Guanfacine is rapidly absorbed following oral administration with a bioavailability of 100 %. The half-life is approximately 21 h after oral dosing. The major metabolite in humans is the 3-hydroxy derivative of guanfacine [100].

Dryness of mouth and sedation are the major *side effects* of guanfacine in the clinic. The incidence of side effects declines considerably with the duration of treatment. The withdrawal syndrome (rise in blood pressure and tachycardia) was seen after abrupt discontinuation of guanfacine in 2 – 4 % of the patients, but was less pronounced than after withdrawal of clonidine. The average dose of guanfacine in clinical trials was 3 mg/d. The optimal effect without side effects was obtained at a single dose of 2 mg [100], [102], [103].

4.1.4. Guanabenz

Guanabenz [*5051-62-7*], 2-[(2,6-dichlorophenyl)methylene]hydrazinecarboximidamide, [(2,6-dichlorobenzylidene)amino]guanidine, $C_8H_8Cl_2N_4$, M_r 231.07, *mp* 227 – 229 °C.

Trade names: Rexitene, Wytensin.

Like clonidine or guanfacine, guanabenz stimulates central α-adrenoceptors and lowers arterial pressure [104–108]. In hypertensive patients oral administration of guanabenz lowers arterial pressure and total peripheral vascular resistance with little or no effect on myocardial function.

In animals or humans guanabenz has no adverse effects on renal function except a slight and transient fall in filtration rate after the first dose [109], [110]. Under certain conditions guanabenz increased excretion of water, and this effect was attributed to the antagonism of vasopressin [111].

In humans guanabenz is well absorbed and exhibits a variable half-life of 7 – 10 h. Less than 1 % of the dose is excreted as unchanged drug. The major metabolites of guanabenz in rat, swine, Rhesus monkeys, and humans are *p*-hydroxyguanabenz and the glucuronide conjugate [110], [112]. Clinical studies demonstrated antihypertensive efficacy of guanabenz at doses from 16 to 65 mg/d [113], [114]. The most common *side effects* of guanabenz are dry mouth, sedation, weakness, and tiredness.

4.2. Drugs with Primarily Peripheral Action

Drugs can inhibit sympathetic transmission at various peripheral sites: (1) sympathetic ganglia, (2) sympathetic nerve endings, or (3) postsynaptic adrenoceptors. Ganglionic blocking drugs were used in the treatment of hypertension 20 to 30 years ago. Hexamethonium [*60-26-4*], a standard ganglionic blocking drug, is still used today as a tool in experimental pharmacology. Typical ganglionic blocking drugs (e.g., pentolinium, chlorisondamine, mecamylamine, and pempidine) block nicotinic receptors at the postsynaptic membrane of the sympathetic ganglia and prevent acetylcholine-induced depolarization. However, they are obsolete in the treatment of hypertension because of unacceptable side effects, which include atony of the gastrointestinal tract, inhibition of gastric and salivary secretion, incomplete emptying of the urinary bladder, cycloplegia, and impotence. These side effects are to a great extent due to the blockade of parasympathetic ganglia. Blockade of sympathetic ganglia can lead to additional side effects, e.g., postural hypotension, syncope, and inhibition of local vasomotor reflexes. Today the only indication remaining for ganglionic blockade is to produce so-called "controlled hypotension"

in surgery in order to reduce bleeding, facilitate small vessel surgery, and improve myocardial performance by reducing preload and afterload. For this indication, trimethaphan camsylate [*68-91-7*] (Arfonad) by infusion is the drug of choice. Its short duration of action permits precise control of blood pressure during infusion and blood pressure returns to control levels immediately after discontinuation of the infusion.

The search for new ganglionic blocking drugs was largely discontinued by 1960. It became clear that hypertension could be controlled by drugs relatively free from the disabling effects accompanying ganglionic blockade. The drugs which replaced the ganglionic blocking agents included diuretics and drugs which inhibited the sympathetic nervous system at loci peripheral to the ganglia; namely, at adrenergic nerve endings or at postsynaptic adrenoceptor sites.

4.2.1. Amine Depleting and Adrenergic Neuron Blocking Agents

At the sympathetic nerve endings drugs can decrease neurotransmitter (norepinephrine) release by depleting it from the storage sites in the nerve terminals or by decreasing the release by stimulation of inhibitory presynaptic α_2-adrenoceptors.

Antihypertensive drugs which lower arterial pressure primarily by an action at the sympathetic nerve endings include reserpine and guanethidine, which are discussed in this section. Other drugs which act by a mechanism similar to that of guanethidine and are marketed in some countries include: bethanidine, guanadrel, debrisoquin, guanacline, and guanochlor. They differ from guanethidine in potency, pharmacokinetics, and some aspects of their pharmacology. The mechanism of their antihypertensive action and the profile of their side effects are, however, not essentially different from those of guanethidine. Orthostatic hypotension is the major side effect which restricts their therapeutic usefulness.

4.2.1.1. Reserpine

Reserpine [*50-55-5*], 11,17-dimethoxy-18-[(3,4,5-trimethoxybenzoyl)oxy]yohimban-16-carboxylic acid methyl ester, $C_{33}H_{40}N_2O_9$, M_r 608.70, *mp* 264 – 265 °C (decomp.), is poorly soluble in water, but is soluble in alcohol, glacial acetic acid, and chloroform. Reserpine was originally isolated from roots of *Rauwolfia serpentina* L. Benth [115].

Synthesis: [116].

Trade names: Alserin, Reserpex, Serpasil.

Reserpine depletes the transmitters from adrenergic, dopaminergic, and serotonergic neurons. Depletion of norepinephrine from adrenergic nerve endings is thought to be primarily responsible for the antihypertensive action of reserpine. The onset of the antihypertensive action is gradual. The maximal effect is seen 6 – 12 h after a single dose of reserpine. The antihypertensive effect is associated with a reduction in cardiac output and in peripheral vascular resistance. After repeated administration cardiac output returns to control values, while peripheral resistance remains at a reduced level [117–119].

Reserpine is well absorbed by oral administration. The major metabolites of reserpine are products of hydrolytic cleavage: methyl reserpate and trimethoxybenzoic acid. Urinary excretion of reserpine metabolites accounts for 20 – 40 % of the administered doses and fecal excretion for less than 10 % [120], [121].

The major *side effects* of reserpine are sedation, nasal stuffiness, and a depressive reaction. Reserpine is also known to increase prolactin release. Adrenocorticotrophic hormone (ACTH) secretion is initially increased and subsequently abolished by reserpine. Gastric secretion is increased and formation of gastric ulcers is promoted. The initial dose of reserpine utilized in hypertension is 0.12 – 1.0 mg/d and the maintenance dose is 0.25 mg or less. The use of reserpine alone has decreased because of the availability of drugs with less severe side effects. In

combination with thiazide diuretics reserpine is, however, still widely used.

4.2.1.2. Guanethidine

Guanethidine [*55-65-2*], [2-(hexahydro-1(-2*H*)-azocinyl)ethyl]guanidine, $C_{10}H_{22}N_4$, M_r 198.31, *mp* 276 – 281 °C.

Trade names: (sulfate salt) Ismelin, Guethine, Iporal, Isobarin.

The major pharmacological action of guanethidine is inhibition of release and of uptake of norepinephrine by sympathetic nerve endings [122–125]. After treatment with guanethidine, vasoconstrictor nerves do not provide reflex compensation to the erect position. Thus, the hypotension after guanethidine is largely orthostatically induced, which can lead to undesirable effects, such as dizziness and syncope. In addition to its adrenergic neuron blocking action, guanethidine has also a direct vasodilator activity, the mechanism of which may involve stimulation of vascular β-adrenoceptors [123], [126]. The hypotensive action of guanethidine can be antagonized by amphetamine, ephedrine, cocaine, or by tricyclic antidepressants [123], [127].

By acute intravenous administrations to animals or humans, guanethidine produces a transient increase in arterial pressure which is followed by hypotension. Peripheral vascular resistance is not changed, while cardiac output is decreased [128], [129]. In chronic oral therapy guanethidine does not change cardiac output [130].

Guanethidine is not completely absorbed from the gastrointestinal tract, with 20 – 25 % of oral dose being recovered from the feces [131]. 2-(6-Carboxyhexylamino)ethylguanidine and guanethidine *N*-oxide have been identified as metabolites of guanethidine [132], [133]. Guanethidine is given once a day at doses ranging from 12.5 to 150 up to 400 mg/d. The doses are adjusted by 10 or 25 mg at 2-week intervals. In addition to orthostatic hypotension, *side effects* of guanethidine include water retention, failure of ejaculation, diarrhea, tenderness in the region of parotid glands, and muscle weakness.

4.2.2. α-Adrenoceptor Antagonists

α-Adrenoceptor antagonists, e.g., phentolamine, tolazoline, or yohimbine, were known for many years [134], but were not used in the treatment of hypertension, because of their questionable effectiveness, rapid development of tolerance, and pronounced reflex tachycardia. The introduction of prazosin [135], [136] and demonstration of its usefulness in the treatment of hypertension resulted in the development of various new α-adrenoceptor antagonists. The selective α_1-adrenoceptor antagonists are more effective in hypertension than antagonists affecting both α_1- and α_2-adrenoceptors. The reduced effectiveness is most likely due to an inhibition of presynaptic α_2-adrenoceptor by nonselective antagonists. This leads to an increase in neurotransmitter release and consequent tachycardia and vasoconstriction, which oppose the hypotensive effects of the drugs as a result of blockade of postsynaptic α_1-adrenoceptors. The three drugs discussed here are relatively selective $\alpha_1$adrenoceptor antagonists.

4.2.2.1. Prazosin

Prazosin [*19216-56-9*], 1-(4-amino-6,7-dimethoxy-2-quinazolinyl)-4-(2-furanylcarbonyl)piperazine, $C_{19}H_{21}N_5O_4$, M_r 382.42, *mp* 278 – 280 °C, is water soluble.

Trade names: Minipress, Hypovase, Sinetens.

The blockade of α_1-adrenoceptors represents the major mechanism of antihypertensive action of prazosin [135–139]. The α_1-adrenoceptor antagonist action of prazosin leads to arterial and venous dilatation, a reduction in preload and afterload, and, consequently, to an improvement in cardiac efficiency. Because of the indirect improvement in cardiac function, prazosin is also

useful in the therapy of heart failure [140]. In spite of pronounced vasodilatation, heart rate undergoes no change or only a slight increase after prazosin [138].

A consistent decrease in peripheral vascular resistance differentiates prazosin from methyldopa, clonidine or β-adrenoceptor antagonists. In spite of pronounced vasodilator action, prazosin in patients either decreases or has no effect on plasma renin activity [141], [142]. The peak plasma concentration of prazosin is reached 2 – 3 h after an oral dose and its half-life is 3.9 h [143]. The major metabolites of prazosin in rats, dogs, and humans are 6-*O*- and 7-*O*-demethylprazosin. Other minor metabolites have been identified [144], [145].

The antihypertensive activity of prazosin is comparable to, or better than, that of methyldopa [146], hydralazine [147], or clonidine [148]. Prazosin is successfully used in combination with thiazide diuretics [149] or β-adrenoceptor antagonists [150].

The major *side effect* of prazosin is the so-called "first dose phenomenon", a syncope in patients receiving a 2-mg tablet as the first dose [151]. The syncope can be avoided if the initial dose is reduced to 0.5 mg and given at bedtime. The dose can then be increased gradually over a 2-week period. Other reported side effects include an increase in the frequency of urination and in the frequency of anginal attacks. The usual dose of prazosin is 2 mg three times a day, but the drug was used at total daily doses up to 20 mg.

4.2.2.2. Indoramin

Indoramin [*26844-12-2*], *N*-[1-[2-(1*H*-indol-3-yl)ethyl]-4-piperidinyl]benzamide, $C_{22}H_{25}N_3O$, M_r 347.46, *mp* 208 – 210 °C. The synthesis and pharmacological activity of indoramin have been described [152–154].

Trade name: (hydrochloride salt) Baratol.

The mechanism of antihypertensive action of indoramin involves primarily the blockade of α_1-adrenoceptors. It is a competitive antagonist of norepinephrine and a noncompetitive antagonist of 5-HT and histamine. At doses higher than required for lowering of arterial pressure (5 vs. 1 mg/kg, i.v. in cats) indoramin reduces sympathetic nerve activity apparently by a central action [154–157]. Other pharmacological effects of indoramin include local anesthetic and antiarrhythmic effects [158], [159].

Indoramin is well absorbed orally. Its mean half-life in humans was estimated to be 5.5 h [160]. The metabolism of indoramin is extensive. The major human metabolite was identified as a conjugate of 6-hydroxyindoramin [161].

Extensive clinical studies have been conducted with indoramin [162–164]. Indoramin is effective in the treatment of hypertension at doses ranging from 20 to 150 mg/d. The major *side effect* is sedation. Indoramin does not produce the "rebound" phenomenon after discontinuation of therapy, nor syncope following the first dose. In addition to its antihypertensive action, indoramin was reported to produce therapeutic benefits in headache and bronchial asthma.

4.2.2.3. Urapidil

Urapidil [*34661-75-1*], 6-({3-[4-(2-methoxyphenyl)-1-piperazinyl]propyl}amino)-1,3-dimethyl-2,4(1*H*,3*H*)-pyrimidine-dione, $C_{20}H_{29}N_5O_3$, M_r 387.49, *mp* 156 – 158 °C, is poorly soluble in water, but readily soluble in dilute acids.

Synthesis: [165].

Trade name: Ebrantil.

Urapidil lowers arterial pressure in hypertensive and normotensive animals. Its antihypertensive activity is due to a combination of peripheral and central actions. The peripheral action involves blockade of α_1-adrenoceptors in vascular smooth muscle. By virtue of its central action urapidil diminishes sympathetic outflow, an effect which is probably mediated by central

α-adrenoceptors and is essentially similar to that of clonidine [166], [167].

Urapidil is well absorbed orally. The maximal blood levels are reached after 0.5 – 1 h after oral administration of tablets and 2.5 – 4 h after administration of slow-release capsules. The plasma half-life of urapidil in humans was estimated as 2.5 – 3.7 h. Urapidil is metabolized by *p*-hydroxylation, *O*-demethylation of the methoxyphenyl ring, and N^1-demethylation of the uracil residue. The same metabolites are found in humans, dogs, rats, and mice. The *p*-hydroxylation product has antihypertensive activity but is less potent than urapidil [167], [168].

In animals, urapidil exhibits sedative activity, while in humans, the major *side effects* include dizziness, headache, and nausea. In the treatment of hypertension, urapidil is effective at 30 – 90 mg/d given as slow-release capsules [167], [169].

4.2.3. β-Adrenoceptor Antagonists

β-Adrenoceptor antagonists were introduced in the treatment of hypertension on the basis of clinical observations that pronethalol, one of the first β-adrenoceptor antagonists, lowered arterial pressure in patients with angina pectoris [170]. The mechanism of antihypertensive action of β-adrenoceptor blocking drugs is still controversial. Various hypotheses have been critically reviewed [171]. Presently, resetting of baroreceptors and the inhibition of sympathetic transmission by blockade of presynaptic β-adrenoceptors are considered the most likely mechanisms of antihypertensive action, although lowering of plasma renin activity and a decrease in cardiac output by β-adrenoceptor antagonists may play a contributory role, particularly in the initial phase of therapy.

β-Adrenoceptor antagonists differ in potency, cardiac selectivity, intrinsic sympathomimetic activity (ISA), membrane stabilizing action (MSA), duration of action, tissue distribution, and metabolism.

A large number of β-adrenoceptor antagonists were developed and marketed during the last decade. The seven drugs discussed are more commonly used and represent different subgroups among β-adrenoceptor antagonists.

4.2.3.1. Propranolol

Propranolol [*525-66-6*], 1-(isopropylamino)-3-(1-naphthyloxy)-2-propanol, $C_{16}H_{21}NO_2$, M_r 259.34, pK_a 9.5, is moderately soluble in water and in ethanol. It is the most commonly used β-adrenoceptor antagonist. The β-adrenoceptor blocking and the antihypertensive activities reside in the (+)-isomer [172].

Trade names: Inderal, Inderex, Docitor, Tesnol, and many others.

Propranolol is not cardioselective; β_1- as well as β_2-adrenoceptors are blocked by the drug. Propranolol has MSA but no ISA. β_2-Adrenoceptor blocking activity can lead to bronchoconstriction and propranolol is, therefore, contraindicated in patients with bronchial asthma. The MSA of propranolol is correlated with local anesthetic as well as with the cardiac depressant actions. At therapeutic doses the MSA of propranolol is not prominent. The negative dromotropic activity of propranolol is evident following acute as well as chronic administration of the drug and is not opposed by the ISA [173], [174].

Following acute intravenous administration to animals or humans, propranolol reduces cardiac output, mean arterial pressure, heart work, left ventricular dp/dt, and blood flow in most vascular beds. Total peripheral vascular resistance is first increased but may be reduced during chronic therapy. Plasma renin activity is consistently reduced by the drug.

Propranolol is nearly completely absorbed from the gastrointestinal tract but is a subject of a large first-pass effect [175]. Peak plasma levels of propranolol are seen within 1 – 3 h after treatment [176]. Propranolol is extensively metabolized; 16 metabolites or conjugates have been identified. The major metabolites are naphthoxylactic acid and 4-hydroxypropranolol (an active metabolite) [177], [178].

In the treatment of hypertension propranolol is usually used at 80 – 320 mg/d in four divided doses, although it was used at doses as

low as 40 mg and as high as 2 g/d. The drug is commonly used in combination with a diuretic and/or a peripheral vasodilator drug [179], [180]. The *side effects* of propranolol include bradycardia, A-V heart block, cardiac insufficiency, bronchoconstriction, cold extremities, fatigue, vivid dreams, or even hallucinations. Rapid withdrawal of propranolol is not recommended because it may lead to coronary insufficiency or myocardial infarction.

4.2.3.2. Metoprolol

Metoprolol [*37350-58-6*], 1-[4-(2-methoxyethyl)phenoxy]-3-[(1-methylethyl)amino]-2-propanol, $C_{15}H_{25}NO_3$, M_r 267.38.

Trade names: Beloc, Betaloc, Lopressor, Lopresor.

Unlike propranolol, metoprolol is relatively specific for β_1-adrenoceptors and is, therefore, relatively free from bronchoconstrictor action [181], [182]. At therapeutic doses, metoprolol has no MSA, and therefore, has no local anesthetic or direct myocardial depressant effects. As a β_1-adrenoceptor antagonist, metoprolol is equipotent to propranolol [183]. Metoprolol is well absorbed by oral administration but has a substantial first-pass effect. Its plasma half-life is 3 – 4 h. Metoprolol is metabolized by *O*-demethylation, subsequent oxidation, oxidative deamination, and aliphatic hydroxylation. The two metabolites, *O*-demethylated product and α-OH-metoprolol, have β_1-adrenoceptor antagonist activity but are 5 times less potent than metoprolol [184], [185].

In clinical studies, metoprolol was shown to be equally effective as hydrochlorothiazide as an antihypertensive agent [186] and either equivalent or superior to other β-adrenoceptor antagonists [183]. In a double-blind study metoprolol was shown to reduce the mortality in patients with myocardial infarction [187].

The *side effects* of metoprolol include tiredness, headache, insomnia, nausea, heartburn, and depression. Withdrawal reactions consisting of headache, malaise, and palpitation were described for metoprolol. Thus, recommendations are to withdraw metoprolol slowly over a 10-d period. The initial dose of metoprolol in the treatment of hypertension is 50 mg twice daily. The maximal daily dose is 450 mg.

4.2.3.3. Nadolol

Nadolol [*42200-33-9*], 5-[3-[(1,1-dimethylethyl)amino]-2-hydroxypropoxyl]-1,2,3,4-tetrahydro-2,3-naphthalenediol, $C_{17}H_{27}NO_4$, M_r 309.42, *mp* 124 – 136 °C, pK_a 9.67.

Trade names: Corgard, Solgol.

Like propranolol, nadolol is not cardioselective and has no ISA. Unlike propranolol, nadolol has no MSA and, therefore, no direct cardiac depressant activity. The therapeutic advantages of nadolol include ability to increase renal blood flow, and a long duration of action (up to 24 h) [188–190]. The oral absorption of nadolol in humans ranges from 20 to 34 %. Serum half-life of nadolol in humans is significantly longer than that of other β-adrenoceptor antagonists and was estimated to equal 24 h [191].

In the treatment of hypertension nadolol is given once a day at 40 – 240 mg [192]. In addition to its antihypertensive effect nadolol was shown to be effective in the treatment of angina pectoris [193] and of certain types of ventricular arrhythmias [194]. Most of the *side effects* of nadolol are similar to those of propranolol.

4.2.3.4. Pindolol

Pindolol [*13523-86-9*], 1-(1*H*-indol-4-yloxy)-3-[(1-methylethyl)amino]-2-propanol, $C_{14}H_{20}N_2O_2$, M_r 248.32, *mp* 171 – 173 °C.

Like propranolol, pindolol is not cardioselective, but unlike propranolol, pindolol has strong ISA, which is responsible for its acute vasodilator effect and for absence of bradycardia. The MSA of pindolol is considerably weaker than that of propranolol. In spite of the absence of cardioselectivity, pindolol is less likely to impair pulmonary function than propranolol, probably because of its strong ISA [195], [196].

Pindolol is well absorbed by oral administration and in comparison with other β-adrenoceptor antagonists, has a lower first-pass effect (13 %) [197]. The plasma half-life of pindolol is 3 – 4 h and the maximal plasma levels are reached 1.5 – 2 h after oral administration to humans [198]. It has a more rapid onset of action than propranolol and after withdrawal has a longer carryover effect [199–201]. The dose range of pindolol in the treatment of hypertension is 10 – 30 mg/d. The drug was initially administered t.i.d. but subsequently the majority of patients were found to respond equally well to once-a-day therapy [202].

The *side effects* of pindolol include insomnia and vivid dreams. Heart failure, heart block, bronchoconstriction, and circulatory disturbances are rare with pindolol.

4.2.3.5. Timolol

Timolol [*26839-75-8*], 1-[(1,1-dimethylethyl)amino]-3-{[4-morpholinyl-1,2,5-thiadiazol-3-yl]oxy}-2-propanol, $C_{13}H_{24}N_4O_3S$, M_r 316.42, is supplied as the hydrogen maleate salt, $C_{17}H_{28}N_4O_7S$, M_r 432.5, *mp* 201.5 – 202.5 °C, which is soluble in water and ethanol and is less lipophilic than propranolol. Unlike other β-adrenoceptor antagonists, timolol is available as the (−)-isomer and not as a racemic mixture.

Trade names: (hydrogen maleate salt) MK-950, Betim, Blocadren, Temserin, Timacor, Timolate, Timoptic, Timoptol.

Like propranolol, timolol is not cardioselective and has no ISA. At therapeutic doses timolol has little or no MSA and has practically no local anesthetic action. As a β-adrenoceptor antagonist timolol is ca. 8 times more potent than propranolol. As a negative inotropic agent timolol is 40 times less potent than propranolol [203–205].

Timolol is rapidly absorbed by oral administration with 72 % of the dose excreted within 84 h. The plasma half-life of timolol in humans was estimated as 5.5 h [206]. Five metabolites of timolol were identified in humans [205]. They have little or no β-adrenoceptor blocking activity.

The clinical study in essential hypertension indicated that timolol at 30 mg and propranolol at 120 mg had comparable antihypertensive activity [207]. Timolol is used in the treatment of hypertension at 10 – 30 mg/d. In patients surviving after acute myocardial infarction, timolol was shown to reduce mortality and reinfarction rates [208]. The *side effects* of timolol include tiredness, dizziness, increase in body mass, and an occasional increase in serum urea and creatinine.

4.2.3.6. Acebutolol

Acebutolol [*37517-30-9*], *N*-(3-acetyl-4-{2-hydroxy-3-[(1-methylethyl)amino]propoxy}-phenyl)butanamide, $C_{18}H_{28}N_2O_4$, M_r 336.43, *mp* 128 – 129 °C. Its *synthesis* and pharmacological activity were first described by Wooldridge [209].

Trade names: Sectral, Neptall, Prent.

Unlike propranolol, acebutolol is cardioselective and has weak ISA and MSA [210–214]. The major metabolite of acebutolol is diacetolol, *RS*-1-(2-acetyl-4-acetyl-amidophenoxy)-2-hydroxy-3-isopropylaminopropane), which has β-adrenoceptor blocking actions similar to those of acebutolol, but has no MSA [215]. The half-life of acebutolol and its metabolite is ca. 4 h. Acebutolol is metabolized in humans almost exclusively to diacetolol, 40 % of which is excreted unchanged [213].

The antihypertensive effect of acebutolol is more pronounced in severe than in mild hypertension [216] and was confirmed in numer-

ous controlled trials [217], [218]. In hypertension acebutolol is given once or twice daily at doses ranging from 200 to 1200 mg/d. *Side effects* of acebutolol include blurred vision, bronchospasm, and bradycardia.

4.2.3.7. Labetalol

Labetalol [*36894-69-6*], 2-hydroxy-5-{1-hydroxy-2-[(1-methyl-3-phenylpropyl)amino]-ethyl}benzamide, $C_{19}H_{24}N_2O_3$, M_r 328.41; the hydrochloride salt, $C_{19}H_{25}ClN_2O_3$, is soluble in water and ethanol. Labetalol has two asymmetric centers and exists as a mixture of four isomers in equal proportions.

Trade names: (hydrochloride salt) Presdate, Trandate.

Labetalol differs from other β-adrenoceptor antagonists in its ability to block not only β- but also α-adrenoceptors, although it is more potent in blocking β-adrenoceptors. As a β-adrenoceptor antagonist, labetalol is not cardioselective, has weak ISA, but has clearly detectable MSA. As an α-adrenoceptor antagonist, labetalol is selective for α_1-adrenoceptors. Because of its α_1-adrenoceptor blocking activity labetalol decreases peripheral vascular resistance, particularly at higher doses. The antihypertensive activity of labetalol is likely to be due to α- as well as β-adrenoceptor blocking effects [219–221].

Following oral administration labetalol is well absorbed and excreted in the form of glucuronide conjugates. The major metabolite is the alcoholic glucuronide of labetalol [221]. Plasma labetalol levels are well correlated with its pharmacological actions [222]. Labetalol experiences high first-pass metabolism [223].

Extensive clinical studies with labetalol were published [224–226]. In humans labetalol lowers arterial pressure without any significant effect on resting heart rate or on cardiac output. It is used in hypertension at 200 – 2000 mg/d, usually in two divided doses. *Side effects* of labetalol include tiredness, dizziness, gastrointestinal disturbances, postural hypotension, impotence, and scalp tingling.

5. Smooth Muscle Relaxants

5.1. Ca^{2+} Channel Antagonists

The Ca^{2+} channel antagonists are a group of vasodilators used extensively in the treatment of angina pectoris (→ Calcium Antagonists, p. 519 ff.). However, their vasodilatory actions extend also to vascular beds other than the coronary and, consequently, their usefulness in hypertension has become apparent. The group classification emanates from the fact that these agents potently inhibit the entry of Ca^{2+} into vascular smooth muscle [227–229], although other mechanisms may contribute to their effectiveness as well [230], [231]. Considerable chemical diversity is found in the representatives of the Ca^{2+} channel antagonists [232], [233]. Nifedipine, nitrendipine, verapamil, and diltiazem have been studied most extensively in the treatment of hypertension; therefore, the emphasis here is placed on these agents.

5.1.1. Nifedipine

Nifedipine [*21829-25-4*], 1,4-dihydro-2,6-dimethyl-4-(2-nitrophenyl)-3,5-pyridinecarboxylic acid dimethyl ester, $C_{17}H_{18}N_2O_6$, M_r 346.34, *mp* 172 – 174 °C, is a yellow crystalline compound, practically insoluble in water, but soluble in organic solvents, such as ethanol, polyethylene glycol, and chloroform. In solution, it decomposes quite rapidly under normal laboratory light.

Trade names: BAY a 1040, Adalat, Procardia, Duranifin, Pidilat.

The structure – activity requirements are reported for several muscle systems, including vascular, cardiac, and nonvascular smooth muscle (see reviews [230], [234]). Specific requirements are the following: (1) the 1,4-dihydro-

pyridine (DHP) ring is essential; (2) an unsubstituted NH-group on the DHP-ring; (3) 2,6-substituents on the DHP-ring should be lower alkyl substituents, but an NH_2 group is acceptable; (4) ester groups in the 3- and 5-positions of the DHP-ring can be substituted to change the vascular selectivity and duration of action; (5) ester groups longer than COOMe will increase activity; (6) the aryl substituent (i.e., phenyl ring) is optimal in the 4-position of the DHP-ring; (7) position of the substituent on the phenyl ring is critical, i.e., *para* results in decreased activity, while *ortho* or *meta* result in increased activity; (8) stereoselectivity is obtained by different ester substitutions on C-3 and C-5 of DHP-ring [235–237].

Nifedipine lowers blood pressure in many experimental models of hypertension [238], [239]. It is efficacious in mild to moderate essentially hypertensive patients [240], [241] and in patients exhibiting severe hypertension [242], [243]. Following oral administration, the antihypertensive responses are rapid in onset (30 – 60 min), with a duration of about 3 h. Nifedipine exhibits diminished activity in normotensive subjects in comparison to hypertensives [240], [244–247].

The antihypertensive effect of nifedipine is due to arterial vasodilatation and a reduced total peripheral resistance [240], [244], [248–252]. Compensatory increases in heart rate, plasma norepinephrine, and renin levels are found after single doses of nifedipine; however, these elevations usually subside during long-term therapy [253–256].

Combined therapy of nifedipine with the β-adrenoceptor antagonists, propranolol or metoprolol, slightly enhanced the antihypertensive response in humans [240], [255]. The addition of methyldopa to nifedipine in severely hypertensive patients increased the antihypertensive response and reduced blood pressure fluctuations between dosing [242].

Sodium and water retention are not a problem during nifedipine treatment. Urinary volume and sodium excretion are elevated in hypertensive patients during nifedipine treatment [257], [258]. Should volume retention occur it can be controlled by diuretic therapy [241].

Nifedipine is bound extensively to plasma proteins (>90 %) [259], [260]. The plasma concentration of nifedipine correlates well to the hemodynamic responses [261], [262]. Metabolism occurs primarily in the liver, with the majority being excreted in the urine and feces as polar metabolites [260], [263].

The *adverse reactions* during therapy include headache, flushing, and nausea. In some patients, a localized ankle edema has been observed, which may be attributed to a change in capillary permeability or perfusion pressure [264]. The oral dosage form is presently approved for use in angina pectoris.

5.1.2. Nitrendipine

Nitrendipine [*39562-70-4*], 1,4-dihydro-2,6-dimethyl-4-(3-nitrophenyl)-3,5-pyridinedicarboxylic acid ethyl methyl ester], M_r 360.4, forms yellow crystals with solubility properties similar to nifedipine; however, nitrendipine is less light sensitive, with a decomposition half-life of about 7 h in laboratory light. It exhibits Ca^{2+} channel antagonism and produces antihypertensive effects in a number of animal models. It is more potent than nifedipine on vascular strips in vitro, and has a longer duration of antihypertensive action in the renal hypertensive dog model [265–275].

Trade names: Bayotensin, Baypress.

Synthesis: [268].

In clinical studies, single or repeated daily oral doses of nitrendipine (5 – 40 mg) effectively lower arterial pressure. The onset of action and peak effects are obtained at 15 min and at 60 – 90 min, respectively. The duration of action is approximately 8 h following a single oral dose, although, with long-term therapy, blood pressure can be controlled for up to 24 h with one dose [276–279]. In hemodynamic studies, nitrendipine lowered total peripheral resistance, but did not significantly affect cardiac output or heart rate [279], [280]. Plasma renin activity and catecholamines levels are increased by nitrendipine, but aldosterone levels are not significantly elevated [280].

In rats and humans, the metabolism of nitrendipine involves dehydrogenation, deesterification, and hydroxylation reactions. The identified metabolites exhibit essentially no antihypertensive activity [265]. *Adverse reactions* in humans include headache, flushing, and nausea.

5.1.3. Verapamil

Verapamil [*52-53-9*], α-(3-{[2-(3,4-dimethoxyphenyl)ethyl]-methylamino}propyl)-3,4-dimethoxy-α-(1-methylethyl)benzeneacetonitrile, $C_{27}H_{38}N_2O_4$, M_r 454.59, is a white crystalline powder, soluble in water, chloroform, and methanol; the compound is not light sensitive. It is a Ca^{2+} channel antagonist which is unrelated chemically to nifedipine and nitrendipine.

Trade names: Isoptin, Calan, Cardibeltin, Cordilox, Vasolan.

Comprehensive reviews and studies on the pharmacology of verapamil have been published [281–287].

In clinical studies, verapamil lowered blood pressure in patients with essential hypertension [288–290]. The dosage ranged between 120 to 160 mg, given three times daily. Total peripheral resistance was decreased and cardiac output was elevated by verapamil. Heart rate was either unchanged or decreased during therapy. The antihypertensive efficacy was directly related to pretreatment levels of blood pressure and inversely related to plasma renin levels [290]. The vasodilator potency when given directly into the forearm circulation was greater in hypertensive patients in comparison with normotensive subjects. In addition, the increase in forearm blood flow correlated positively with basal concentrations of plasma epinephrine but not with plasma levels of renin or aldosterone [291]. Verapamil fails to elevate plasma catecholamine, renin, or aldosterone levels. The mechanism responsible for this effect is unknown; however, possibilities might involve catecholamine depletion, a decreased neuronal norepinephrine release, or depressed baroreceptor reflex sensitivity [292–296]. Constipation is the most prevalent *side effect* of verapamil therapy [283].

5.1.4. Diltiazem

Diltiazem [*42399-41-7*], 3-(acetyloxy)-5-[2-(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-1,5-benzothiazepin-4(5*H*)-one, $C_{22}H_{26}N_2O_4S$, M_r 414.52, is a white crystalline powder, freely soluble in water, methanol, or chloroform. The chemical synthesis of diltiazem and related substances has been reported [297], [298].

Trade names: Cardizem Herbesser, Dilzem.

The vasodilator structure – activity relationships have been reported and summarized [299–301]. Diltiazem is the D-*cis* isomer. The *trans* isomeric forms exhibit much lower vasodilator activity. Other substitutions which result in lower activity include replacement of the methoxy group with a hydroxyl group or additional alkoxy substituents on the aromatic ring. In addition, removal of the alkyl-aminoalkyl group at N_5 will significantly reduce the activity, as will dealkylation or quaternization of the terminal nitrogen. Other alterations, such as replacement of the methoxy group by a *p*-methyl and chlorine substitution at the 7-position of a condensed aromatic ring, do not reduce activity.

The antihypertensive activity of diltiazem has been demonstrated in DOCA, renal, and spontaneously hypertensive rats [302–304]. Diltiazem increased cardiac output, significantly elevated cardiac and skeletal muscle blood flow, and produced lesser flow increases to the mesenteric, cerebral, and renal vascular beds. Flow to the skin is usually unchanged or reduced by diltiazem [301], [305–307].

In humans, diltiazem is effective in mild-to moderate hypertension at oral doses ranging between 180 – 270 mg/d. The reduction in blood pressure (−10 to −15 %) was accompanied by an increase in cardiac output. Similar to preclinical studies, heart rate was not increased and plasma catecholamines were only moderately

increased [308]. In another study, intravenous diltiazem (0.2 mg/kg plus 0.1 mg/kg-min, i.v.) dilated both arterioles and larger conduit arteries in hypertensive patients. These results contrasted with dihydralazine which dilated arterioles, but constricted larger arteries [309].

Details on the mechanism of action and other pharmacological properties of diltiazem have been summarized [305]. Metabolism occurs primarily in the liver. Primary biotransformation entails demethylation of the terminal nitrogen, cleavage of the *p*-methoxy group, and oxidative hydroxylation of the aromatic rings. The 3-hydroxy compound is a major metabolite which exhibits some pharmacological activity [301], [310].

5.2. Vasodilators with Other Mechanisms of Action

Vasodilator drugs with a direct action on vascular smooth muscle were used in the therapy of hypertension long before the discovery of Ca^{2+} channel antagonists. Among vasodilator drugs hydralazine is the most commonly used drug, although its precise mechanism of action is still controversial. The common pharmacological properties of these drugs can be summarized as follows:

1) Their hypotensive activity is independent of the sympathetic tone.
2) They antagonize the vasoconstrictor effects of various endogenous substances including norepinephrine, serotonin, angiotensin II, and K^+.
3) Their site of action is at the membrane of vascular smooth muscle, at the contractile elements, or on the enzymatic processes involved in the delivery of energy for the contractile activity.
4) Their common side effects include tachycardia, salt and water retention, myocardial necrosis, and hyperglycemia.

5.2.1. Hydralazine

Hydralazine [*86-54-4*], 1-(2*H*)-phthalazinone hydrazone, $C_8H_8N_4$, M_r 160.18, *mp* 172–173 °C, is a yellow crystalline substance, soluble in acetic acid. Hydralazine has been available for the treatment of hypertension for about 30 years.

Trade names: Apresoline HCl, Hydralazine HCl; (combination with hydrochlorothiazide) Apresoline-Esidrix, Apresozide, Hydrap-ES; (with reserpine) Serpasil-Apresoline; (with hydrochlorothiazide plus reserpine) Ser-Ap-Es.

Hydralazine lowers arterial pressure in many experimental models of hypertension. Certain structure requirements are necessary for maximal activity. Among the more important requirements are the presence of a free NH_2 group and the placement of the hydrazino-group in the 1-position of the phthalazine moiety for optimal duration of action. The activity is affected minimally with the substitution of a carbon in the phthalazine or a pyridine replacement of the benzene ring [311].

Antihypertensive actions of hydralazine result primarily from arteriolar relaxation and a decreased peripheral resistance, with essentially no effects on venous tone. Heart rate and cardiac output are increased by hydralazine. The cardiotonic action results primarily from reflex adjustments to the decreased arterial pressure (baroreceptor reflex) [312] or quite possibly from elevation in central venous pressure (Bainbridge reflex) [313]. In addition, a direct cardiac stimulant effect has been observed in anesthetized dogs by some [314], but not by other investigators [313]. The direct and reflex actions of hydralazine are antagonized by propranolol. Cardiac hypertrophy occurring in SHR is not attenuated by hydralazine, whether given alone or in combination with propranolol [315]. Extensive pharmacological studies with hydralazine were published [316–328].

Clinically, the antihypertensive effect of hydralazine is enhanced by the addition of β-adrenoceptor antagonists, reserpine, guanethidine, methyldopa, clonidine, or diuretics [329], [330]. When given in combination with venodilators (e.g., isosorbide dinitrate or nitroglycerin) hydralazine has proved especially useful in the treatment of congestive heart failure [331].

5.2.2. Diazoxide

Diazoxide [*364-98-7*], 7-chloro-3-methyl-2*H*-1,2,4-benzothiadicazine-1,1-dioxide, $C_8H_7ClN_2O_2S$, M_r 230.70, *mp* 330 – 331 °C, is chemically related to chlorothiazide and other benzothiadiazine diuretics, but it exhibits no diuretic activity. It is an effective antihypertensive agent in spontaneous, DOCA, and renal hypertensive rat models [332], [333]. Antihypertensive doses of diazoxide, when given intravenously, range between 2 and 10 mg/kg in animal studies. The duration of action is dose-related and ranges between 0.5 – 4 h.

Trade name: Hyperstat I.V.

When given intravenously, diazoxide reduces total peripheral resistance and increases stroke volume and cardiac output [334].

In humans, heart rate and force of left ventricular contractions are increased by diazoxide, while left ventricular systolic and end-diastolic pressures are decreased. β-Adrenoreceptor blockade attenuates the elevations in heart rate and in left ventricular dp/dt, but augments the reduction in left ventricular systolic pressure [335]. The mechanism of action of diazoxide remains to be fully elucidated [336–340].

Hyperglycemia is observed during diazoxide therapy. This effect is attenuated by propranolol [341] and the ganglionic blocker chlorisondamine [342]. The propensity of diazoxide to cause hyperglycemia, and Na^+ and fluid retention has restricted its clinical use to acute life-threatening hypertensive emergencies. The dosage is titrated on the basis of individual responsiveness, but ranges between 100 and 300 mg, i.v. [343].

5.2.3. Minoxidil

Minoxidil [*38304-91-5*], 6-(1-piperidinyl)-2,4-pyrimidinediamine-3-oxide, $C_9H_{15}N_5O$, M_r 209.25, *mp* 248 °C, 259 – 261 °C (decomp.), is a white crystalline solid. Minoxidil is primarily a dilator of arterial vasculature, thereby lowering total vascular resistance and blood pressure.

Trade name: Loniten.

Extensive literature on pharmacology of minoxidil exists [344–353].

Minoxidil is approved primarily for use in severely hypertensive patients who do not respond to maximal therapy with a diuretic or other antihypertensive agents, or in patients where side effects preclude other drug therapy. It is also useful in moderately hypertensive patients [354], those with impaired renal function [355], but is used rarely in hypertensive emergencies because of its availability in oral dosage form only and its long onset of action [345]. Minoxidil is combined with β-adrenoceptor blockade to reduce effects of reflex sympathetic activation. It is also effective when combined with other centrally acting sympatholytics, such as clonidine [356], or methyldopa, α-adrenoceptor antagonists, or neuronal blocking agents [357]. Captopril has been used as an adjunct to minoxidil in refractory hypertensive cases [358]. Because of sodium and water retention, a diuretic is given in almost all cases; however, this may not be necessary in patients with less severe hypertension [345].

The use of minoxidil is limited to a relatively small population of hypertensive patients because of the incidence of hypertrichosis, and potential for the occurrence of atrophic and ischemic lesions of the heart [359]. The hypertrichosis occurs in about 80 % of the patients treated. It occurs about 3 – 6 weeks after the onset of therapy and requires about 1 – 6 months for recovery after discontinuation of minoxidil. Cell culture experiments showed that minoxidil may produce the hypertrichosis by a direct action on epidermal cells [360].

5.2.4. Sodium Nitroprusside

Sodium nitroprusside [*14402-89-2*] is used as the dihydrate, $Na_2Fe(CN)_5NO \cdot 2\,H_2O$, M_r 216.91, readily soluble in water, but decomposes in light.

Trade names: Nipride, Nitropress.

Nitroprusside is not absorbed orally and thus must be given by systemic infusion. Vasodilatory effects are exerted on both the arterial and venous sides of the vasculature. Infusion of sodium nitroprusside at 1 to 100 $\mu g\, kg^{-1}\, min^{-1}$ produces a uniform fall in systolic and diastolic blood pressure. The onset of action is usually rapid (< 60 s) and the effect is well-maintained during the infusion. Recovery of blood pressure occurs rapidly following cessation of drug [361]. This most likely is the result of rapid cellular degradation of sodium nitroprusside. Because of this rapid recovery the magnitude of the hypotensive response can be controlled easily by varying the infusion rate. Tolerance to repeated sodium nitroprusside infusions occurs rarely [362]. Other pharmacological effects have been described [363–367].

The vasodilator activity of sodium nitroprusside is attributed to the NO-group (nitroso) [368–370]. The vasorelaxant effects do not directly involve α- or β-adrenoceptors and are quite fully manifested when vessels are contracted by angiotensin or vasopressin. Sodium nitroprusside may reduce the transsarcolemmal influx of calcium or enhance calcium efflux by stimulating $Na^+ - K^+$ ATPase, although quite disparate data have been found in both regards [371–373]. Elevations in cellular levels of cyclic GMP are intimately involved in the vasodilatory responses [369], [370].

A final metabolic product of sodium nitroprusside is thiocyanate. Toxicity during prolonged infusions is usually due to thiocyanate accumulation (i.e., hypoxia, nausea, tinnitus) and necessitates discontinuation of treatment.

6. Perspectives in the Development of Antihypertensive Drugs

A large number of new antihypertensive drugs have been introduced during the last 30 years. These drugs were usually justified by an improved side effect profile and/or by a more physiological mechanism of action. This trend is likely to continue during the next decade. Many new inhibitors of angiotensin converting enzyme have been introduced. The effectiveness of Ca^{2+} channel antagonists in the treatment of hypertension was recognized and novel inhibitors of Ca^{2+} channels are likely to be developed during the next decade. Drugs interfering with intracellular Ca^{2+} translocation, e.g., calmodulin inhibitors, also can be conceivably useful in the treatment of hypertension.

The central control of arterial pressure by drugs is receiving renewed attention. The recognition of the importance of various neurotransmitters, e.g., 5-HT, GABA, dopamine, in the central regulation of cardiovascular functions is likely to lead to novel antihypertensive drugs with central mechanism of action. Modification of the synthesis or release of various neuropeptides may also represent a future mechanism of antihypertensive action. The role of vasopressin in the cerebral as well as peripheral control of vascular tone has received renewed attention, and vasopressin antagonists can conceivably be useful in the treatment of hypertension.

The importance of the "natriuretic hormone" in the control of Na^+ levels in vascular smooth muscle cell and consequently of Ca^{2+} levels is now being recognized, and drugs controlling the release or the effects of "natriuretic hormone" may be useful in the treatment of hypertension.

7. Summary and Conclusions

In spite of the discovery of two new classes of antihypertensive drugs, inhibitors of the angiotensin converting enzyme and Ca^{2+} channel antagonists, the well-established antihypertensive drugs, such as diuretics and β-adrenoceptor antagonists, are still being widely used.

Diuretics which do not produce hypokalemia, hyperuricemia, hyperglycemia, or hyperlipoproteinemia, or diuretics with an additional direct vasodilator action are still in demand and may be introduced in the near future.

The novelty of the mechanism of action as well as the clinical efficacy and safety will help to expand the market for converting enzyme inhibitors. Their apparent usefulness in the treatment of heart failure will also contribute to the expansion of their market share.

Among drugs which interfere with the sympathetic nervous system, α_1-, β-, and α_1/β-adrenoceptor antagonists are widely used in the treatment of hypertension. The advantages of

α_1-adrenoceptor antagonists (e.g., prazosin) include increase in blood flow to vital organs and lowering of peripheral vascular resistance. βAdrenoceptor antagonists control arterial pressure with minimal side effects, and reduce mortality in patients with myocardial infarction. It remains to be seen whether new α_1/β-adrenoceptor antagonists (e.g., labetalol) will combine the benefits of both types of drugs.

With the discovery of the antihypertensive action of Ca^{2+} channel antagonists the interest in the direct acting smooth muscle relaxants has been renewed and drugs which interfere with vascular smooth muscle tone and affect intracellular calcium translocation are likely to be introduced in the near future.
